Soil waterlogging also is a major environmental stress that suppresses soybean (*Glycine max* (L.) Merr.) growth and yield. A study was conducted with the goal of identifying QTL associated with the tolerance of soybean to soil waterlogging, where 208 recombinant inbred (RI) populations were subjected to 2 weeks of waterlogging when the plants were at the early flowering stage (Vantoai *et al.*, 2010). A single QTL was identified, linked to marker Sat_064, from the Archer parent which was associated with improved plant growth (11–18%) and grain yields (47–180%) in waterlogged environments.

In maize (*Zea mays* L.) soil waterlogging is also a major environmental stress that affects growth and yield. To identify the QTL associated with waterlogging tolerance at the maize seedling stage, an F_2 population consisting of 288 $F_{2:3}$ lines were created from a cross between two maize genotypes, 'HZ32' (waterlogging-tolerant) and 'K12' (waterlogging-sensitive) (Qiu *et al.*, 2007). A total of 25 and 34 QTLs were detected in two experiments, respectively. The effects of each QTL were moderate, ranging from 3.9% to 37.3%. Several major QTL determining shoot dry weight, root dry weight, total dry weight, plant height, and their waterlogging tolerance coefficient each mapped on chromosomes 4 and 9. These QTLs were detected consistently in both the experiments. Secondary QTLs influencing tolerance were also identified and located on chromosomes 1, 2, 3, 6, 7, and 10. These QTLs were specific to particular traits or environments.

Genetic Engineering

The terms GE or genetic modification (GM; also used for 'genetically modified') have been used for the processes of transforming plants (Lawlor, 2013). Crop GE with signaling components and transcription factors (TFs) lead to the expression of their target transcriptome that consists of several genes involved in stress adaptation. However, only a few crops, such as rice (Xiao *et al.*, 2009; Oh *et al.*, 2009), maize (Nelson *et al.*, 2007; Castiglioni *et al.*, 2008), and canola (Brassica napus) (Vanderauwera *et al.*, 2007; Wang *et al.*, 2005), expressing the desired TF and other genes, have been tested

under real field stress conditions. GE-derived crops still have a long way to go to gain universal acceptance and reach farmers' fields. Even though the benefits to small and resource-poor farmers have been demonstrated and the GE technology is becoming more popular, the political will to facilitate this process is weak (Farre *et al.*, 2010). Indeed, there have been many calls for the global harmonization of regulations, which would make the requirements compatible and consistent (Ramessar *et al.*, 2008). Regulatory harmonization would help remove artificial trade barriers, expedite the adoption of GE crops, protect developing countries from exploitation, and bring the benefits of GE products to the consumer. Eventually, the adoption of biotech crops to mitigate abiotic stresses that are expected to increase in frequency and intensity in coming years will depend on public perceptions and public acceptance, as well as on cultural and institutional processes in developing countries (Varshney *et al.*, 2011).

Climate Change on the Future of Plant Breeding

With the climate change a new scenario is established. The higher temperatures will reduce crop productivity. An increase in CO_2 concentration is certain with both direct and indirect effects. The increase in the frequency of drought, the increase in the areas affected by salinity, and the increase in the frequency of biotic stress are also highly probable (Ceccarelli *et al.*, 2010).

The developing world already contends with chronic food problems. Climate change presents yet another significant challenge to be met. The estimate for Africa is that 25–42% species habitats could be lost, affecting both food and non-food crops. Habitat change is already underway in some areas, leading to species range shifts, changes in plant diversity which includes indigenous foods, and plant-based medicines (McClean, 2005). In developing countries, 11% of arable land could be affected by climate change, including a reduction of cereal production in up to 65 countries, approximately 16% of agricultural GDP (FAO, 2005).

The considerable efforts needed to prepare for climate-related impacts and the time required for agriculture, forestry, and fishery production systems to adapt is the crucial point. Success depends on factors relating to biology, ecology, technology, and management regimes. Those countries with limited economic resources and insufficient access to technology will be least able to keep up with the changes (FAO, 2007).

The future is always uncertain, but it is what we will live in. In the scenario of climate change, these uncertainties are even greater. Despite all technological advances, models of climate forecasts in the medium and long term will still need to be corroborated. It is, however, not known, how much the impact will increase and the effect it will cause on the planet and the living creatures in it.

Numerous research efforts in all knowledge areas are being implemented to mitigate as much of the predicted problems as possible. In this scenario, given that plant breeding has been a success story in increasing yield, it can help in developing new cultivars with enhanced traits better suited to adapt to climate change conditions using both conventional and genomic technologies (Dixon *et al.*, 2006; Habash *et al.*, 2009). These traits include drought and temperature stress resistance, resistance to pests and disease, which continue to cause crop losses, salinity, and water logging (Humphreys, 2005; Oerke, 2006). The genetic improvement of plants, based on experiences of the past, is an area that can make contributions to the adaptation of plants to the new agricultural scenario of the coming years (Ramalho *et al.*, 2009).

Experience has shown that biotic and abiotic stresses occur together, although not necessarily all at once. Normally, when temperatures are elevated, water stress on plants is strong and pest incidence, among other stresses increases. To identify more tolerant cultivars to all these factors the available alternative, with proven efficiency, is to evaluate the progeny and/or cultivars in the conditions in which the crops will be grown (Ramalho *et al.*, 2009).

In this context, the main drawback to the work of breeders is the interaction of genotypes with environments. In other words, genotypes respond differently to environmental stimuli. Therefore, especially under tropical conditions, where the diversity of climate and management adopted by farmers is higher, the interaction of genotype by environment is the greatest challenge to be met. Cultivars must be well adapted and more stable.

Glossary

Climate change A change in the state of the climate that can be identified (e.g., by using statistical tests) by changes in the mean or the variability of climate properties and that persists for an extended period, typically decades or longer. Climate change may be due to natural internal processes or external forces or due to persistent anthropogenic changes in the composition of the atmosphere or in land use.

Climate change adaptation An adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities.

Climate change mitigation A human intervention to reduce the human impact on the climate system; it includes strategies to reduce greenhouse gas (GHG) sources and emissions and enhance GHG sinks.

Command-and-control policy In the climate change case, this involves a government-imposed limit on greenhouse gas emissions where the limit should reflect a balance between the damages from emissions and the cost of reducing emissions.

Externalities Occur when a change in the production or consumption of an individual or firm affects indirectly the well-being of another individual or firm. Externalities can be positive or negative.

Greenhouse gas (GHG) Those gaseous constituents of the atmosphere, both natural and anthropogenic, that absorb and emit radiation at specific wavelengths within the spectrum of thermal infrared radiation emitted by the Earth's surface, the atmosphere itself, and by clouds. This property causes the greenhouse effect. Water vapor (H_2O), carbon dioxide (CO_2), nitrous oxide (N_2O), methane (CH_4), and ozone (O_3) are the primary GHGs in the Earth's atmosphere. Moreover, there are a number of entirely human-made GHGs in the atmosphere, such as the halocarbons and other chlorine- and bromine-containing substances, dealt with under the Montreal Protocol. Besides CO_2, N_2O, and CH_4, the Kyoto Protocol deals with the GHGs sulfur hexafluoride, hydrofluorocarbons, and perfluorocarbons.

Private party adaptation Adaptation actions initiated by private agents acting in their own best interests. Such individuals alter operations to better adapt to climate. This is also often called autonomous adaptation.

Public party adaption Actions collectively implemented by governments or other societal organizations. Generally, this resolves adaptation deficits arising due to public goods characteristic where private party adaptation is insufficient, so public agencies have to step in to take actions.

Tradable emission permits In the climate change case, this involves a government-imposed limit on GHG emissions in the form of permits for emissions but allows the permits to be traded.

Transactions costs When GHG offsets are sold, the transactions typically will involve cost. These are three types of transaction costs: (1) preproject costs that include search costs, negotiation costs, baseline determination costs, approval costs, validation costs, review costs, and registration costs; (2) project implementation costs that include monitoring costs, verification costs, review costs, certification, and enforcement costs; and (3) trading costs that include transfer costs and registration costs.

Introduction

In recent decades, climate change has become a popular and controversial topic debated intensively worldwide. This is mainly due to the complex, distinctive features of the climate change issue, such as the uneven distribution of effects and emissions, global and long-term causes, and key interrelationships with energy and economic growth. In this study, the authors have examined aspects of climate change as observed and projected, causal factors, policy approaches, and findings. Throughout the article, the authors have emphasized economics and agriculture and forestry (AF).

Basics of Climate Change

A lot of scientific endeavor has been devoted to documenting what has been happening with climate change, why this might be happening, and what is likely to happen? Here, the authors have overviewed some of that literature as background to the reset of the document.

What Have been Seen?

Many have assembled data, showing that the world is facing growing global temperatures (see the NOAA data represented in **Figure 1**, IPCC (2007a), and the United States Global Change Research Program (USGCRP)). Such data show that 11 of the 12 warmest years in the Earth's recorded history have happened since 2000.

In addition, reports like the IPCC (2007a,b) or the National Academy of Sciences (2011) show a long list of effects including (1) global sea level is rising; (2) ice melting in the past 25 years that took 1600 years to form; (3) rainfall patterns are changing; and (4) weather is becoming more extreme, leading to costly events, including huge losses in the agricultural sector. For example, the Texas Extension Service estimates that the drought in the US Southwest in 2011 entailed net loss of US$7.6 billion.

Why is This Happening?

Many acknowledge that they see the climate change, although there is not a broad social consensus on the causality. However, scientists are largely arguing that societal emissions of greenhouse gases (GHGs) are a strong causal factor. For example, the IPCC (2007a) states "Since pre-industrial times, increasing emissions of GHGs due to human activities have led to a marked increase in atmospheric GHG concentrations," whereas the United States National Academy states "Climate change, driven by the increasing concentration of greenhouse gases (GHGs) in the atmosphere, poses serious, wide-ranging threats to human societies and natural ecosystems around the world" (Fri *et al.*, 2010). Globally, IPCC (2007d) estimates that 69% of the GHGs originate from energy consumption, whereas 14% arise from food production and 17% from deforestation. Meanwhile, energy use, food use, and land use change, and thus emissions generally expand with incomes and population. In fact, historical emission data show that global GHG emissions and concentrations have been increasing at an increasing rate (**Figure 2**). Society has tried to mitigate GHG emissions but is making slow progress. Climate stabilization requires that emissions peak then drop to low levels (Fri *et al.*, 2010). Unilateral action by any one country would not be effective and thus has to be a global endeavor.

What is Projected?

Given continuing emissions, a changed future climate is expected in terms of temperature changes, as projected in **Figure 3**, along with associated precipitation and other changes (Knutti and Sedláček, 2012). In turn, this would cause changes in such things as fresh water supplies; snow pack; location of agricultural crop production; extreme event incidence; sea level; coastal inundation; and pest, diseases, bird, animal, and plant ranges.

Damages and Economic Dimension

Before probing into policy responses to this multifaceted issue, the authors have reviewed damages and economic effects.

Is Climate Change Causing Economic Damages?

Climate system changes affect many items, some beneficial, detrimental, minor, and major with differential effects across

locations and periods (Tol, 2014). Market influences can also spread the effects to many sectors. Suppose the supply of goods from one sector shrinks due to climate change effects then the price of those goods will go up accordingly. If this commodity is used as an input to produce another commodity (for instance, corn is a feed for cattle) then the production cost of the other commodity will increase as its sale price. For consumers, higher prices will give rise to less consumption and smaller consumers' surplus. Producers, as Adams *et al.* (1990) found, may benefit from higher prices. Nonetheless, in most cases, total welfare will decrease due to climate change effects.

Numerous economic studies have examined climate change effects on production and welfare.

Contribution of Working Group I to the Fourth Assessment Report of the Intergovernmental Panel on Climate Change. Cambridge University Press, Cambridge.

Production

With regard to the agricultural sector, climate change can alter yields and crop acreage (Adams *et al.*, 1990, 1999; Reilly *et al.*, 2002; IPCC, 2007b). Climate change has diverse implications involving the effects of carbon dioxide, temperature, precipitation (amount, distribution, and intensity), and extreme events (droughts, hurricanes, floods, etc.). All of these, in turn, alter production, as a number of authors have reviewed.

Using a historical statistical approach, Chen *et al.* (2004) found that crop yield effects of temperature and precipitation changes varies with crop. This has been subsequently verified by others (Tack *et al.*, 2012; Schlenker and Roberts, 2009). Studies have also investigated the effects of climate extremes, such as hot days, standard deviation in temperature, precipitation intensity, and droughts (McCarl *et al.*, 2008; Huang and Khanna, 2010). Studies have also been carried out using crop simulators finding temperature and precipitation effects (Parry *et al.*, 2004; Tubiello *et al.*, 2002; Backlund *et al.*, 2008; Iglesias *et al.*, 2012).

Yield effects also arise from increased atmospheric concentrations of carbon dioxide, where it serves as a fertilizer, simulating some species of crops to grow faster (C3 crops, including wheat, potatoes, etc.; Darwin and Kennedy, 2000). However, this is not the case for C4 crops (corn, sorghum, etc.), where benefits appear to arise only under moisture stress (Leakey, 2009). Attavanich and McCarl (2011) included this in a statistical investigation by merging the United States Department of Agriculture data with crop data from field-level free air carbon enrichment experiments (Long *et al.*, 2006) finding that in some cases yields are substantially influenced and possibly confused with technical progress.

Changes in crop production also affect crop prices, economic returns, and land allocation with substantial shifts projected (Adams *et al.*, 1990, 1995, 1999; Reilly *et al.*, 2002; McCarl, 2011).

Climate change can also alter resources for production. Kjellstrom *et al.* (2009) concluded that heat exposure caused

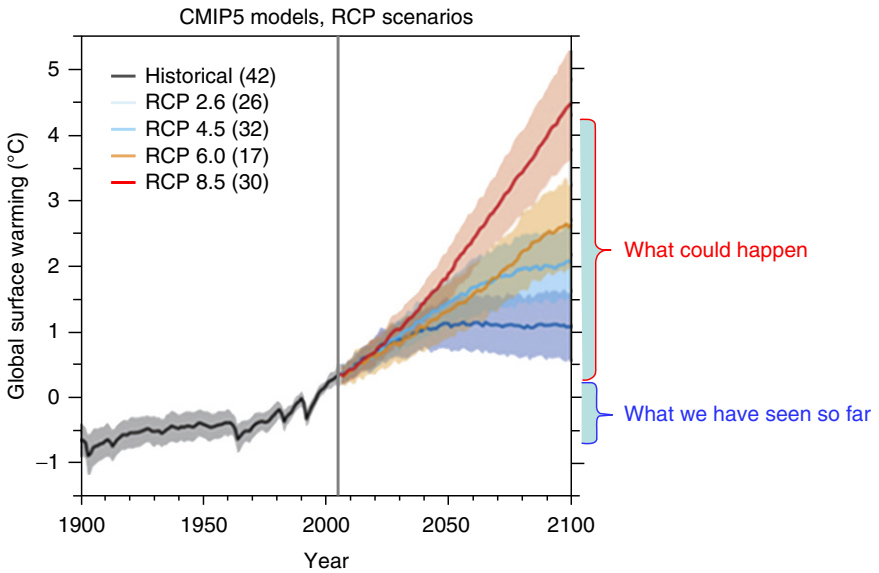

Figure 3 Global temperature change from new coupled model intercomparison project phase 5 (CMIP5) climate model projections. RCP, representative concentration pathways. Adapted from Knutti, R., Sedláček, J., 2012. Robustness and uncertainties in the new CMIP5 climate model projections. Nature Climate Change 3, 369–373.

by global climate change may substantially impair labor productivity. A number of authors have examined water finding regionally detrimental effects (Gleick *et al.*, 2000; Bates *et al.*, 2008; Chen *et al.*, 2001).

Welfare

Efforts have been made to estimate the economic consequences of climate change on agriculture in terms of land values and social welfare in terms of producer income and measures of consumer satisfaction. A series of studies initially found climate change to be detrimental for the welfare of those involved with agriculture but as the crop scope, carbon dioxide effects, and adaptation possibilities were added, it became beneficial (Adams *et al.*, 1990, 1995, 1999; Reilly *et al.*, 2002; McCarl, 2011). However, others argued that it would be detrimental, and appraisals in countries like Mali, Butt *et al.* (2005) certainly showed that. In terms of land value, Mendelsohn *et al.* (1994) analyzed a cross-section dataset consisting of 3000 counties in the United States and found that higher annual temperatures reduced average farm values. Broader scoped studies have shown varying results depending on location with some regions benefiting but some warm regions losing (see the review and results in Van Passel *et al.*, 2012).

In terms of water resource effects, Hurd and Rouhi-Rad (2012) and Adams and Peck (2008) stated that climate change effects on water give rise to economic welfare loss through lower consumer surplus resulting from higher water prices and costs of actions taken due to water shortage.

Forestry is sensitive to climate change as well. However, Alig *et al.* (2002) showed that in the United States small welfare increases would arise. In terms of global timber markets, Sohngen and Mendelsohn (1998) found that supply of timber would increase and bring benefit to the whole timber market.

In terms of more aggregate measures, Tol (2014) reviewed 17 multisector studies and concluded that the initial net effects are positive but they become negative in the long run.

All in all, as shown above, climate change poses a serious and persistent threat to portions of the world and to increasingly larger parts as changes become larger.

If Greenhouse Gases Are Causing Climate Change, Why Are They Still Emitted?

Up to here, the authors have built the argument that climate change is occurring, in all likelihood caused by GHG emissions, and such emissions are more likely to continue increasing the degree of climate change. Furthermore, this climate change has caused changes in production and welfare plus portends future risks as it proceeds. The next question then is: Why do the emissions proceed? In economics, such emissions are commonly called an externality. GHGs are not purposefully emitted; they are rather a by-product emission from activities such as energy generation/use, agricultural fertilization, livestock raising, coal mining, cement manufacture, and many other activities. Furthermore, there is generally not a direct way that people damaged by climate change now and in the future can reflect the damages they incur on those now involved in the generation of the GHG emissions. In more concrete terms, the carbon dioxide emitted by industrial activities increases the level of GHGs in atmosphere and causes some degree of climate change. In turn, climate change causes some damage, but those who are damaged bear the costs without any compensation. Furthermore, they have no way of reflecting those costs on the entities causing the emissions. Such an effect is the externality, resulting in a greater degree of GHG emissions than desired, which economists call a market failure.

There are complex issues involved with potential resolution of the externality. One aspect is that GHG emissions reduction is a public good (Tol, 2014), with everyone living on the earth potentially benefitting without reducing the utility others gain. In turn, this motivates free riding activity with parties motivated to enjoy the benefits of reduction without paying for it. Another aspect is that gasses spread globally and reductions by any one party or country have small implications, thus coordinated global emissions reductions are required (Stern, 2007; Fri *et al.*, 2010). Yet another aspect is that GHG emissions have persistent impacts spanning decades, benefitting parties in the future, but the costs of reducing them are borne by current parties raising intergenerational equity concerns. Other complex characteristics include the following: uncertainties associated with the long-run implications of emissions (a precise estimate of economic effects is not possible and is debatable), irreversible economic damages are possible, tipping points may be involved, effects are unevenly distributed across regions and social strata, and nonmarginal change (IPCC, 2007b; Stern, 2007; Fri *et al.*, 2010).

Basic Policy and Social Action Approaches

Three broad policy and social action approaches have been used to address the climate change issue and a fourth is possible. One involves investing in the development of information on the climate change degree, consequences, and potential outcomes (monitoring and projecting consequences). There are also three damage-reducing approaches. These are commonly called adaptation, mitigation, and geoengineering.

- Mitigation involves actions aimed at reducing the magnitude of climate change drivers, like reducing GHG emissions. Such actions are designed to reduce current and future atmospheric concentrations. In turn, such actions are designed to limit future climate change along with ocean acidification (IPCC, 2007d; Fri *et al.*, 2010).
- Adaptation involves actions to reduce the damage arising from a given amount of climate change plus exploiting the positive opportunities. This involves manipulating management, information dissemination, infrastructure investment, and enterprise choice to improve coping mechanisms.
- Geoengineering (also climate engineering) involves purposeful intervention in the Earth's climatic system with the aim of reducing climate change. The two basic thrusts involve solar radiation management and carbon dioxide removal (Izrael *et al.*, 2009). The subject is controversial and

widely debated (Barrett, 2007; Boyd, 2008; Robock, 2008; Schneider, 2008; Pelley, 2009; Bellamy *et al.*, 2012). Interested readers are referred to those references and the topic will not be further discussed here.

Note that these basic policy directions are not mutually exclusive and the first three are currently being used to various extents plus there is considerable room for increasing activities in all three spheres. In this study, the authors have discussed these directions in more detail.

Information Efforts

Information Value

One policy approach where there has been a lot of investment involves information development. Coping with climate change involves decisions across multiperiods based on information available to decision makers. Under climate change, decisions are often made in the face of uncertainty and are adjusted over time. In fact, information on climate change and its impacts are insufficient today. First, science and technology have not been developed yet to accurately assess and predict climate change. There are still numerous unexplored problems associated with climate change. Moreover, it is costly to collect and disseminate all relevant information, particularly in developing countries (Berrang-Ford *et al.*, 2011; Bryan *et al.*, 2009; Deressa *et al.*, 2009).

Because the information is crucial for decision making, there is implicit value associated with it. The authors have used Figure 4 to shed light on the value of information within the climate change context. Here, they focus mainly on information for adaptation. Similar arguments can be extended to mitigation decisions.

The curves in Figure 4 represent different agricultural productions in terms of value of activity on land in response to climate variables, for instance, temperature in this case. As temperature goes up to specific levels, the production should switch from one crop to another in order to maintain the highest possible value. For example, temperature T_1 is the threshold for switching between wheat and corn, whereas T_2 is the threshold for switching between corn and grazing. In this example, the authors assume that actions are taken instantaneously against climate change.

Under temperature T_3, a rational farmer would plant wheat with realized land value at Point B. Now consider the temperature changes from T_3 to T_4 due to climate change. The farmer would change the crop from wheat to corn, ending up with land value at Point A. However, this adaptive action requires that the farmer possesses complete information about climate change before cropping decisions are made. If the farmer is unaware of the ongoing climate change, wheat can still be planted on the land, which results in the value of planting wheat at Point C. Planting wheat generates less value than planting corn under temperature T_4. Hence, the value loss ΔV due to lack of information could be interpreted as the value of information associated with climate change.

In the face of information needs to aid decision making, large investments have been made in information generation, particularly involving the following:

- Developing information on how the climate has been changing globally, regionally, and locally; the forces causing these changes; the nature of natural and human responses; economic consequences; projections of future levels of causal agents; climate change; and economic consequences. Certainly the long-standing efforts by the IPCC (1990, 1996, 2001, 2007a,b,c,d and the ongoing fifth assessment effort) and country efforts like the United States (USGCRP and National Academy studies) fall into this domain.
- Developing information on possible policy actions and their effectiveness. Many studies have worked on the role of information on adaptation (National Academy of Sciences, 2011; United Nations Framework Convention on Climate

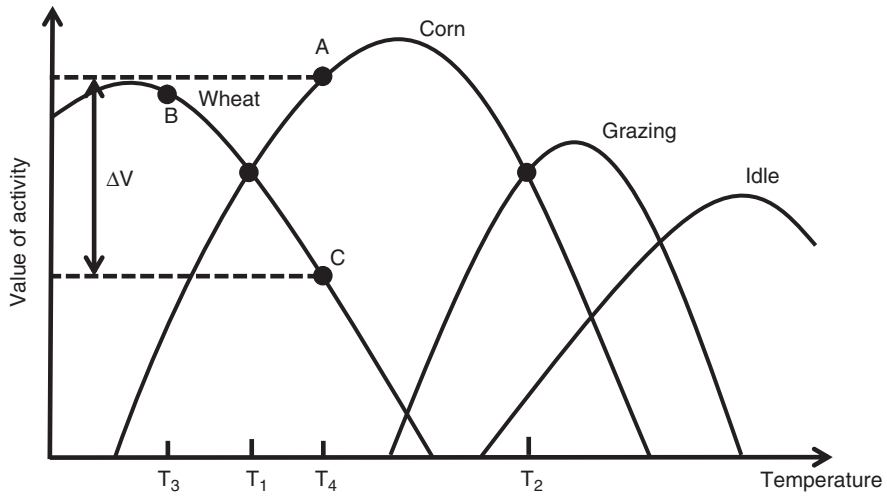

Figure 4 Value of activity on land in response to temperature. Adapted from Mendelsohn, R., Nordhaus, W., Shaw, D., 1994. The impact of global warming on agriculture: A Ricardian analysis. American Economic Review 84 (4), 753–771 and Kelly, D.L., Kolstad, C.D., Mitchell, G.T., 2005. Adjustment costs from environmental change. Journal of Environmental Economics and Management 50(3), 468–495.

Change (UNFCCC), 2007; World Bank, 2010), mitigation (IPCC, 2007d; National Academy of Sciences, 2011), social dimensions (Mearns and Norton, 2010), and geoengineering (Bellamy *et al.*, 2012).

Information and Dynamic Decision Making

It is generally impossible for people to accurately predict the future climate and the consequences of alternative GHG concentrations. Consequently, climate change decision making involves a series of decisions and revisions as time and information grows. A number of studies suggest utilizing flexible approaches to cope with climate change that can benefit from continuous learning/information accumulation (Berkhout *et al.*, 2006; Pelling *et al.*, 2008; Leary, 2009; Fri *et al.*, 2010; Hallegatte *et al.*, 2011).

Climate Change Mitigation

The first active policy considered relative to climate change involved mitigation (or limiting GHG emissions) and thereby the future extent of climate change (Fri *et al.*, 2010). The United Nations formed the Framework Convention on Climate Change in 1994, and today there are 195 countries that are Parties to the Convention. The convention aims "to stabilize greenhouse gas concentrations at a level that would prevent dangerous anthropogenic (human induced) interference with the climate system." In 1997, the UNFCC formulated the Kyoto Protocol, which commits its parties by setting internationally binding GHG emission reduction targets and remains in force for much of the world today.

AF will be directly or indirectly involved in mitigation as these sectors are both emitters and providers of sinks that sequester GHGs in the ecosystem. This merits explicit mention in the Kyoto protocol that mentions emissions from enteric fermentation, manure management, rice cultivation, soil management, field burning, and deforestation along with sinks of afforestation and reforestation. In the following sections, the AF in climate change mitigation are discussed, followed by economics of the issue, and then some challenges and future research needs.

Policy Approaches to Climate Change Mitigation in Agriculture and Forestry

Externalities have long affected society, and various methods have been formulated to deal with them. Classically, one basically tries to reflect the costs imposed by the emissions on the emitter generally by the government in a way to improve private decision making and the market result (Mankiw, 2012). This has been done by regulation, taxation/subsidization, and imposition of trading schemes. Their basic characteristics are as follows:

- Regulation or command-and-control policy involves a government-imposed limit on GHGs emissions, where the limit should reflect a balance between the damage from emissions and the cost of reducing emissions. Obviously, command-and-control policy is a simple and direct approach to reduce emissions. But, in order to determine the appropriate level of emission regulation, government needs thorough knowledge of the regulated activity and the damage caused plus an ability to monitor and enforce compliance. Also, the burden of the regulation can be quite different depending on the emitters' production characteristics possibly causing substantial inequities (Tol, 2014).
- Emissions taxation involves imposing a cost to emit, whereas subsidies give benefits to emissions reductions. Nordhaus (2008) stated that the appropriate taxation level should represent the discounted present value of damage resulting from an additional ton of emissions. The tax acts like a penalty that will be paid by people emitting GHGs. While imposing the tax, the government needs to know this appropriate tax level but is uncertain in terms of the amount that emissions will be reduced (Mankiw, 2007). Generally, subsidies have similar effects as taxes in the short run, but one of the differences from taxes is the redistribution of money (Tol, 2014): in terms of taxes, money is transferred from consumers to governments; in terms of subsidy, the trend of money flows reverse, that is, from governments to consumers.
- Tradable emission permits involve a government-imposed limit on GHGs emissions in the form of permits for emissions but allows the permits to be traded. It permits emitters that would incur high cost in reducing emissions to buy permits from those who can reduce emissions at a lower cost, lowering the overall cost of emissions (Nordhaus, 2008). The Kyoto protocol advocates such a scheme and spawned the multisector, multicountry European Union's Emissions Trading Scheme in 2005.

Generally speaking, economists prefer market-based trading or taxation methods to direct market regulation. Through such mechanisms, policy makers internalize the externality: providing emitters with incentives to reduce emissions and innovate in developing new, lower emitting technologies (Nordhaus, 2008).

Recently, attention has been paid to voluntary participation in emission reduction programs with emitters allowed to opt in and choose to produce carbon offsets. If emitters choose to join the program (opt in), then they are going to be directly paid for the GHG abatement and will also be provided with liability for any future GHG emissions. Also, AF is generally mentioned as sectors that are not capped but ones that may sell emission reductions or sequestration increases into the market place.

Beyond the market and command-and-control approaches, a number of other policy approaches are possible. For example, Fri *et al.* (2010) mentioned:

- Pursuit of near-term emission reductions including (1) increasing energy efficiency in production and use/conservation and (2) increasing the use of low GHG-emitting electricity generation like those relying on renewables, new-generation nuclear power, power plants equipped with carbon capture and storage technology, and low GHG-emitting transportation options.
- Accelerated retirement, retrofitting, or replacement of emissions-intensive infrastructure.
- Increased research and development on low-emitting technology choices.

How Agriculture and Forestry Can Participate in Mitigation Efforts?

IPCC (2007d) presents estimates that AF are the source of approximately 30% of anthropogenic GHG emissions mainly in the form of methane, nitrous oxide, and carbon dioxide. Main sources for methane emissions are rice, ruminants, and manure. For nitrous oxide, main sources are manure, legumes, and fertilizer use. For carbon dioxide, the main emissions arise from fossil fuel usage, soil tillage, deforestation, other land-use change, biomass burning, and land degradation.

AF management can be altered to reduce emissions by a number of means. For example, in many cases management can be improved, cattle diets can be changed, fertilization practices altered, tillage and associated energy use reduced, irrigation pumping efficiency improved, rice management altered, land moved into more perennials, and many other strategies (McCarl and Schneider, 2000).

In terms of sinks, AF annually absorb atmospheric CO_2 as plants and trees grow, and then release it as they decay. Retention (sequestration) can be increased in soils and standing vegetation by altering practices. Such practices include cropland retirement (conversion to native vegetation), residue management, less-intensive tillage, land use conversion into pasture, afforestation, restoration of degraded soils, avoided deforestation, longer forest rotations, and forest management practices, can contribute to mitigation and storing carbon in wood products (McCarl and Schneider, 2000; Krankina and Harmon, 2006; Wilson, 2006).

Fossil fuel-intensive products can also be replaced with substitute products of AF. Certain AF products can be used to replace building materials, such as steel and concrete. Also, AF biomass can directly be used in fueling electrical power plants or can be processed into liquid fuels, such as ethanol and biodiesel. Using biomass as energy feedstocks reduces net CO_2 emissions because the carbon in the feedstock is drawn from the atmosphere via photosynthesis. However, this offset is not perfect as feedstock's growth, refining, and related transport emits GHGs. Furthermore, one must also consider the leakage or indirect land-use effects when land is diverted from traditional commodity production resulting in potential land conversion or other emissions increasing activities elsewhere (Murray *et al.*, 2004; Searchinger *et al.*, 2008; Fargione *et al.*, 2008). Other potentially significant indirect negative effects, such as rebound effects in energy consumption due to changes in the price of energy, are also probable (Rajagopal *et al.*, 2010).

Economic Work on Costs of Agriculture and Forestry Greenhouse Gas Mitigation

There have been a wide variety of efforts addressing the extent to which AF can produce cost-competitive supplies of GHG net emission reductions. These studies have looked at the issue in terms of particular strategies and across a portfolio of strategies. In terms of individual strategies, McCarl and Schneider (2000) reviewed cost estimates across a variety of emission reductions, sequestration, and substitute product options.

In terms of individual strategy appraisals:

- A long history of forest sequestration studies show that cost-competitive possibilities exist in terms of afforestation and forest management (Moulton and Richards, 1990; Adams *et al.*, 1993, 1999; Parks and Hardie, 1995; Plantinga *et al.*, 1999; Stavins, 1999; IPCC, 2000; Stavins and Newell, 2000; Kauppi and Sedjo, 2001; Sohngen and Mendelsohn, 2003; Latta *et al.*, 2011). Later, studies enter more complexity and show increased costs of offsets (Latta *et al.*, 2011).
- Agricultural soil carbon has been shown to be competitive at lower prices (Pautsch *et al.*, 2001; Antle and Capalbo, 2001) but of relatively short duration (15–20 years or so for tillage and up to 50 years for land-use change; West and Six, 2007).
- The cost-competitive sequestration amount has been found to be substantially lower than the total estimated potential with the differences narrowing as carbon price increases (McCarl and Schneider, 2001).
- A large number of studies have looked at individual agricultural emissions reduction and biofuel strategies as reviewed by McCarl and Schneider (2000), IPCC (2007d), and Smith *et al.* (2006).

In terms of portfolios:

- A range of emission reductions and offsets have been found to be cost-effective strategies for GHG offsets with different ones being superior at alternative price levels (McCarl and Schneider, 2001; Murray *et al.*, 2005; Baker *et al.*, 2010).
- Large potential options include agricultural soil carbon and forest management at low prices and in the near term with afforestation and bioenergy in the longer term (Lee *et al.*, 2007; Murray *et al.*, 2005).
- Competition between strategies significantly alters results from single-strategy appraisals. For example, soil carbon increases as price initially increases but then falls at high levels in favor of forestry and bioenergy (McCarl and Schneider, 2001; Schneider and McCarl, 2003; Lee *et al.*, 2007).
- Agricultural emission offsets are competitive with food production. For example, McCarl and Schneider (2001) found substantial decreases in food production and increases in food prices at higher carbon prices.

Renewable energy has been found to have a large role in achieving ambitious climate mitigation targets (McCarl and Schneider, 2001; Schneider and McCarl, 2003; Murray *et al.*, 2005; Hoogwijk *et al.*, 2009), but effects on market prices and sequestration in key areas, like rainforests, are a major concern. Johansson and Azar (2007) focused on the competition between bioenergy and food production and found a similar result. Searchinger *et al.* (2008) and Fargione *et al.* (2008) argued that such results would be expected.

Distributional Effects of Mitigation and Cobenefits

Distributional effects of mitigation strategies have been examined. A number of studies show that mitigation activity stimulated by GHG prices generally improves producers' welfare and decreases consumers' welfare (McCarl *et al.*, 1999; United States Department of Agriculture, Global Change Program Office, 1999; Konyar and Howitt, 2000; McCarl and Schneider, 2001; Schneider and McCarl, 2005; Baker *et al.*,

2010). Murray *et al.* (2005) showed that effects and strategies used vary regionally. Sparovek *et al.* (2009) showed that welfare effects may be negative across different societal groups with some regions/groups experiencing losses. Also, some mitigation policies also benefit other environmental or economic items. For instance, Elbakidze and McCarl (2007) discussed the coeffects of mitigation on water and air quality; however, they also indicated that full consideration of these benefits was quite complex.

Challenges in Mitigation

Although many studies show that AF may be able to supply low-cost mitigation opportunities, it is important to consider some challenges raised in the Kyoto protocol. These are commonly known as additionality, leakage, permanence, and uncertainty. It is also important to consider transaction costs.

- *Additionality* For economic efficiency, mitigation activities need to provide GHG emission reductions that are additional to what would have occurred in the absence of mitigation activity. However, actors who adopt strategies in advance of a mitigation program generally have an interest in being paid for their actions. Murray *et al.* (2007) discussed this issue.
- *Leakage* Another mitigation challenge is leakage. Leakage embodies the idea that mitigation gains in one place could be offset due to mitigation-induced reductions in commodities produced and offset, emissions increasing, and production elsewhere. Mitigation options like diverting land from production of food crops to bioenergy crops or afforestation may lead to emission increasing agriculture expansion elsewhere. The result is a lower effect on emissions (Murray *et al.*, 2004) and possibly an emission's increase or a long-term emission's debt (Searchinger *et al.*, 2008; Fargione *et al.*, 2008).
- *Permanence* Certain activities only provide offsets for a limited time and store potential emissions. In particular, biological sequestration in soils and standing trees only uptake carbon until equilibrium is reached (West and Six, 2007) and on practice reversal, the stored carbon is released. This raises the possibility of a price discount for such activities as discussed by Kim *et al.* (2008).
- *Uncertainty* There is uncertainty in the magnitude of the GHG offsets developed by many potential AF projects due to the effects of forces like climate, fire, and pests. Kim and McCarl (2009) discussed possible discounts and the value of widely spread portfolios.
- *Transactions costs* When GHG offsets are sold, the transactions typically will involve cost. Michaelowa and Jotzo (2005) classified transaction costs for GHG projects into three different groups: (1) preproject implementation costs that include search costs, negotiation costs, baseline determination costs, approval costs, validation costs, review costs, and registration costs; (2) project implementation costs that include monitoring costs, verification costs, review costs, certification, and enforcement costs; and (3) trading costs that include transfer costs and registration costs. There would also be costs of brokers assembling projects as discussed in Post *et al.* (2009) and Kim (2011).
- *Other difficulties* Costs and benefits of mitigation can arise over a long period. Discounting of impacts over long time horizons can be problematic (Weitzman, 2007; Dietz and Stern, 2008). Also, many impacts are extremely complex and their consideration and monetary valuation can be complicated. Moreover, there are usually no compensation mechanisms that may well balance costs and benefits among different stakeholders (Söderholm and Sundqvist, 2003).

Adaptation in Climate Change

There is a likely inevitability to a substantial amount of climate change. GHG emissions and atmospheric concentrations are on a strong increasing upward trend, whereas climate stabilization requires close to zero net emissions. IPCC (2007c) presents a series of atmospheric GHG stabilization scenarios and these show substantial climate change, even if GHG emissions peak now and then trend toward zero. In such a setting there is a need to address adaptation to a changed climate (Rose and McCarl, 2008).

Adaptation is used in a climate change setting to refer to "adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities" (IPCC, 2007b). Some studies have shown that with adaptation AF could, to a large extent, moderate the damage caused by lower levels of climate change (Easterling *et al.*, 1993; Adams *et al.*, 1999; Reilly and Schimmelpfennig, 1999; Yu and Babcock, 2010; Zilberman *et al.*, 2012).

Who Adapts?

Climate adaptation can be initiated by actors across multiple levels, such as individuals, firms, and public entities. In general, such adaptation actions are undertaken by private and public parties with important distinctions.

Private party adaptation (also called autonomous adaptation – IPCC, 2001; Smith *et al.*, 2000) is initiated by private agents acting in their own best interests. Such individuals are altering operations in reaction to climate. Much private party adaptation has been done in AF for centuries (McCarl, 2007). Adaptations can be observed today. For example, in AF, Seo and Mendelsohn (2008a) found evidence of shifts in livestock populations as climate evolves, whereas Mu *et al.* (2013) found evidence of land use and stocking rate shifts and Park (2012) found evidence of crop mix shifts.

Public party adaptation, sometimes called planned adaptation, is collectively implemented by governments or other societal organizations. Activities in this domain correct for market failures in the classical public good sense (Samuelson, 1954) where private parties do not reap the full gain of adaptation or where private parties cannot adapt due to limited resources, knowledge, or capability (Speranza *et al.*, 2010; Hallegatte *et al.*, 2011).

Means of Agriculture and Forestry Adaptation

A wide variety of adaptation actions are possible. In managed AF settings, private adaptation decisions include altering

planting and harvesting date, crop varieties, crops mix, livestock species, irrigation, pest management strategy, shade provision, insurance use, fire control, etc. (Klein *et al.*, 1999; McCarl, 2007). In unmanaged AF ecosystems, natural adaptation is occurring but perhaps at an undesirable pace and thus shifting to more active management may be possible. On the public side, a number of possible strategies can be pursued, including the following, as summarized by McCarl (2007):

- Research investment in crop varieties, management practices, etc.
- Extension investment in disseminating adaptation information.
- Infrastructure investment in transport, flood control, water provision, coastal protection, etc.
- Adaptation adjustment assistance, like education, migration of facilities, etc.
- Support for new industries, developing new institutions, and relocating industry, etc.
- Trading policy allowing more imports or exports to alleviate lost production and cope with surpluses.

Economic Aspects of Agriculture and Forestry Adaptation

A number of studies have addressed economic aspects of adaptation. These can be separated into studies of climate change offset ability, observed historical levels of adaptation, and modeling adaptation in an economic sense.

Basic AF adaptation concept

Figure 4 above shows the basic adaptation concept. In particular, a producer will pick the production system that is most economically attractive, given the climate regime at a location. Suppose that the curves in Figure 4 show the returns to various enterprises on a parcel of land as the temperature varies. In turn, under a temperature level of T_3, a rational farmer would plant wheat as it is superior to the other possibilities. Now suppose the temperature rises from T_3 to T_4, then the farmer would adapt by changing from wheat to corn to seek higher economic returns. Further temperature increases cause additional shifts as well.

Climate change offset ability

Adaptation can reduce the adverse effects of climate change to some extent or enhance the benefits. For example, technological advances, such as genetically modified crops and more efficient irrigation systems, can help to maintain agriculture productivity at the level before climate change. Adams *et al.* (1995) and Tubiello *et al.* (2002) found that changes in planting date and crop maturity can substantially improve production. Yu and Babcock (2010) showed that yield losses of corn and soybeans in the United States Corn Belt from drought have decreased over time due to effort being devoted to research on drought-tolerant crops. Adams *et al.* (1999) showed that changes in crop mixes have substantial benefits.

Observed adaptation

Contemporary adaptation has been examined by looking at how AF practices vary over space and respond to climate conditions over time (Chen and McCarl, 2001; Seo and Mendelsohn, 2008a,b; Seo *et al.*, 2009a,b). For example, findings indicate variations in many fields:

- observed agriculture yield, where changes under climate change are smaller than agronomic results, indicating that effective adaptation is occurring (Mendelsohn and Dinar, 2003);
- input usage associated with climate, where, for example, Chen and McCarl (2001) found increased pesticide costs incurred as climate got warm;
- mix of animals and crops (Seo and Mendelsohn, 2008a,b; Mu *et al.*, 2013);
- land allocation between crops and livestock (Seo and Mendelsohn, 2008a; Mu *et al.*, 2013);
- crop varieties and planting dates (Tubiello *et al.*, 2000); and
- livestock breeds (Zhang *et al.*, 2013).

Modeled adaptation

A number of studies have tried to examine potential adaptations by predicting their nature and implications using modeling. In such efforts, adaptation can only employ possibilities portrayed in the model, so it is important to have an augmented set of production possibilities that can be used in the face of climate change. A number of findings have arisen from such studies. For example:

- There are significant adaptation benefits from alterations in cropping systems, planting dates, harvest dates, and varieties (Adams *et al.*, 1995, 1999; Easterling *et al.*, 1993; Tubiello *et al.*, 2000, 2002).
- Crop mix shifts are more likely beneficial (Adams *et al.*, 1999) but cause shifts in needed infrastructure (Attavanich *et al.*, 2013).
- Adaptation can alter income effects substantially and reduce the risk of hunger effects (Butt *et al.*, 2005, 2006; Reilly *et al.*, 2002).
- Producers in low- to mid-latitude forests can adapt using short rotation plantings, bringing down timber prices (Sohngen *et al.*, 2001; Spittlehouse and Stewart, 2003).

Effort Allocation and Economic Tools for Climate Change Analysis

Effort Allocation between Information, Mitigation, and Adaptation

One big question involves the societal allocation of effort between conventional matters and climate change-related efforts. Conceptually, this involves an allocation problem considering the opportunity costs of allocated funds and their marginal returns in various climate change activities (McCarl, 2012). Some economic studies have dealt with the allocation issue regarding adaptation and mitigation (de Bruin *et al.*, 2009; Wang and McCarl, 2013).

Economic Tools

Many studies have been done regarding climate change issues. Broadly speaking, these have involved a statistical, spatially observed data approach and a simulation, structural approach

(Schimmelpfennig *et al.*, 1996). In the remaining of this study, the authors have provided a few comments on the nature, strengths, and weaknesses of both.

Statistical spatial modeling

Statistical, spatial-based models examine climate change effects, adaptation, and mitigation using historical data on practices employed and their consequences. Typically, statistical or econometrical approaches over panel datasets are used, separating those factors that could account for different effects in different places. In the effects and adaptation arenas, one looks at data across space and time characterized by alternative climates and can infer the following: (1) effects of climate change on land values (Mendelsohn *et al.*, 1994), crop yields (Chen *et al.*, 2004), or input use (Chen and McCarl, 2001) or (2) adaptation in terms of land use (Mu *et al.*, 2013), crop mix (Park, 2012), livestock species (Zhang *et al.*, 2013), or livestock type (Seo *et al.*, 2009b). In the mitigation arena, one looks at how productivity is altered by adoption of mitigation strategies and infers the cost of achieving mitigation (Antle and Capalbo, 2001).

Advantages of this method are that the behavior of farmers and changes in the environment are both embedded in the data and in the estimated model and one can control a number of factors, like soil quality (Adams *et al.*, 1998). Disadvantages are that prices are assumed to be constant, that there is generally no cost for farmers or companies to adapt to climate change, and that the model cannot completely capture phenomena in the dataset or beyond the range of the dataset (like high CO_2 levels) (McCarl *et al.*, 2010).

Structural modeling

A structural modeling approach generally combines biophysical and economic models under climate change data to project the effects of climate change issues (Lambi and Molua, 2007). In general, it uses an assumed behavioral economic model often based on mathematical optimization. For instance, researchers often used welfare maximization under climate change to simulate market reactions (Adams *et al.*, 1990, 1999; Reilly *et al.*, 2002).

The strength of this approach is that it presents comprehensive responses and adjustments from physical and economic aspects of agriculture to climate change examining phenomena beyond the scope of the current data (Schimmelpfennig *et al.*, 1996). For instance, Butt *et al.* (2005) and Arndt *et al.* (2012) used structural methods to simulate the effects of climate change in developing countries without large data requirements. Also, changes in market prices can be captured and then employed in welfare analysis (Adams and Hurd, 2002).

However, this type of model assumes the motivation for decision making (i.e., profit maximization) and the mechanism for market clearing. The strength of the adaptations and mitigation modeling is purely dependent on the production possibilities included in the model (Adams *et al.*, 1998; McCarl *et al.*, 2010) and can lead to under- or overestimates (Adams and Hurd, 2002). Another problem associated with this method is that one usually extends the conclusions of some regionally specific experimental cases to more general and diverse agricultural situations (Schimmelpfennig *et al.*, 1996).

Combined methods

Even though the authors categorize the above as two different methods, the relationship between them is often complementary, instead of mutually exclusive (Schimmelpfennig *et al.*, 1996; Lambi and Molua, 2007). For example, the United States national assessment used a combination of both modeling approaches in its appraisal (Reilly *et al.*, 2002).

Concluding Comments

The authors have reviewed the evidence for climate change, the causes and the projections followed by a review of possible information, adaptation, and mitigation actions. In the discussion, they have attempted to provide the reader with an introduction to the vast literature by extensive referencing. Given the vastness of the issue, this was intended only to be an introduction and a guide to where one might go to learn more.

Cloning Animals by Somatic Cell Nuclear Transplantation

PJ Ross and C Feltrin, University of California, Davis, CA, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Clone An organism that is an exact genetic copy of another.
Cryopreservation Maintenance of viable tissues, cells, or embryos at very low temperature.
Enucleation The process of removing the recipient cell chromosomes or nucleus.
Epigenetics Heritable changes to DNA and its associated proteins that control/establish gene expression patterns without affecting the underlying DNA sequence.
Nuclear reprogramming The process of returning a differentiated cell nucleus to a totipotent state.
Recipient cytoplast An oocyte that has had its DNA removed.
Somatic cell nuclear transfer (SCNT) A technique that allows the production of cloned animals.
Transgenic animal An animal in which there has been a deliberate modification of its genome, such as addition or deletion of genes.
Zona pellucida (ZP) A glycoprotein membrane that surrounds the plasma membrane of the oocyte.
Zygote The one-cell embryo formed by the union of sperm and oocyte.

Introduction

Animal Cloning and Nuclear Reprogramming

A clone is an organism that is an exact genetic copy of another. Many plants and animals in nature utilize cloning as a form of reproduction. Somatic cell nuclear transfer (SCNT) is a technique that allows the production of cloned animals. With this technique, the nucleus of a donor cell, containing an animal's genetic material, is introduced into an enucleated oocyte called the recipient cytoplast. Embryonic development is then induced and, providing that the right conditions are maintained, the reconstructed embryo can develop into an individual that will be genetically identical to the one from which the nuclear material was derived (**Figure 1**).

The process by which the somatic cell nucleus is transformed into an embryo is called nuclear reprogramming and involves changes to the epigenetic mechanisms that control gene expression and cell differentiation status. Most cells in an organism contain the same genetic information, which is stored in their deoxyribonucleic acid (DNA). Epigenetics refers to heritable changes to DNA and its associated proteins (collectively referred to as chromatin) that control/establish gene expression patterns without affecting the underlying DNA sequence. As embryonic cells differentiate into different tissues and cell types, the DNA remains the same, but the cells acquire different epigenetic modifications. The normal development of an embryo and fetus depends on a precise sequence of chromatin configuration changes, which are usually related to methylation of genomic DNA and modifications to the histone proteins to which DNA is wrapped around. These epigenetic changes are heritable from cell to cell and are acquired in a progressive and sequential manner as cells differentiate. The presence of these epigenetic marks and their ability to be passed to daughter cells after cell division is a mechanism to maintain the functional and differentiation status of the cells. This mechanism explains why when a cell in the skin divides, its daughter cells continue to be skin cells and do not turn into neurons or any other cell type. It was thought that development of an embryo to an adult was a unidirectional process and the differentiation status of a cell, and thus its epigenetic modifications, were fixed and irreversible. Cloning using adult differentiated somatic cells disproved that dogma (Gurdon, 1962; Wilmut *et al.*, 1997), demonstrating the enormous plasticity of the mammalian epigenome. Successful cloning by SCNT involves epigenetic reprogramming whereby the gene expression profile and the epigenetic memory of the differentiated cell is abolished and the new embryo-specific gene expression and epigenetic profile is established, driving correct embryonic and fetal development. This includes abrogation of the expression of approximately 8000–10 000 genes in the somatic cell and initiation of the embryonic program with approximately 10 000 genes (Niemann and Lucas-Hahn, 2012). Failure to reprogram the donor genome is thought to be the main reason for the low efficiency of cloning (Rideout *et al.*, 2001; Bourc'his *et al.*, 2001; Dean *et al.*, 2001). Thus, cloning efficiency depends on the ability of donor cells to be totally reprogrammed to an embryonic state and the ability of the recipient cytoplasm to reprogram the exogenous (i.e., donor) nucleus.

The oocyte is one of the few cells that have the ability to induce the necessary changes to a somatic cell nucleus, so that embryonic development can proceed to term. This capacity probably extends from the natural role oocytes have during normal development. When the oocyte and sperm, two highly differentiated cells, meet at fertilization in order to generate a new individual, their genomes must be combined and rendered amenable to embryonic and fetal development. This process includes extensive and dynamic epigenetic remodeling.

Historical Perspective

The original idea of generating an animal from a somatic cell was proposed by Spemann in the early 1900s (Spemann, 1914) as a way to test the developmental potential of a cell's

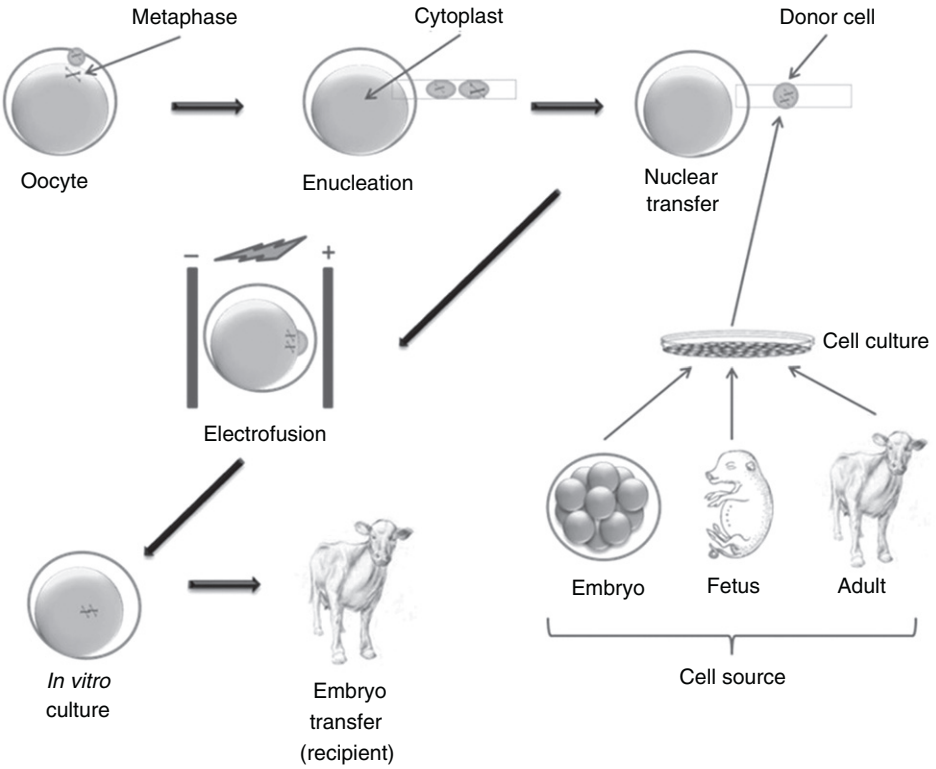

Figure 1 Cloning animals by nuclear transplantation.

nucleus. However, the required technology to perform Spemann's proposed experiment was not available until the 1950s, when Briggs and King developed nuclear transfer techniques in amphibians (*Rana pipiens*), obtaining adult animals when injecting embryonic cells into enucleated oocytes (Briggs and King, 1952). In 1962, John Gurdon used a similar technique to produce frogs (*Xenopus tropicalis*) from intestinal cells, demonstrating that a somatic cell nucleus has all the genetic material necessary for development of a complete individual (Gurdon, 1962). Gurdon was awarded the Nobel Prize for these accomplishments.

In mammals, nuclear transfer technology was developed several decades later as technological improvements allowed scientists to work with the smaller mammalian embryos. The transfer of an embryonic nucleus into an enucleated mouse zygote (1-cell embryo) was reported by Illmensee and Hoppe in 1981, resulting in the development of adult animals (Illmensee and Hoppe, 1981). However, controversy surrounded these results, as other groups were unable to replicate them. McGrath and Solter (1983) developed a more efficient technique by which the donor cell was fused with, instead of being injected into, an enucleated zygote; however, they were not able to produce offspring when two-cell and older embryos were used as cell donors. In 1986, Willadsen used sheep mature oocytes as recipient cytoplasts instead of zygotes and was able to obtain offspring after the transfer of cells from early stage cleavage embryos (up to a 32-cell embryo) (Willadsen, 1986). The embryo cloning approach developed by Willadsen provided the opportunity for producing a limited number of clones from a single embryo. This technique was then successfully applied to several species, including cattle (Prather *et al.*, 1987), rabbits (Stice and Roblm, 1988), pigs (Prather *et al.*, 1989), mice (Kono *et al.*, 1991), and monkeys (Meng *et al.*, 1997), with some commercial companies providing embryo-cloning services for more than a decade.

In the mid-1990s, Keith Campbell and Ian Wilmut hypothesized that synchronizing the cell cycle of the donor and recipient cells could be the key to efficiently cloning from adult animal cells. Their experiments led first to successful cloning from embryonic cells cultured *in vitro* (Campbell *et al.*, 1996) and soon after to the birth of the first mammal cloned from an adult somatic cell – Dolly the sheep (Wilmut *et al.*, 1997). Dolly was cloned from a somatic cell nucleus derived from mammary gland cells cultured *in vitro*. Only one viable animal was produced from the 277 reconstructed embryos created, a relatively low efficiency that remains unimproved to this day. After the sheep was cloned, several other mammalian species followed, including the cow (Cibelli *et al.*, 1998), mouse (Wakayama *et al.*, 1998), goat (Baguisi *et al.*, 1999), pig (Polejaeva *et al.*, 2000), gaur (Lanza *et al.*, 2000), mouflon (Loi *et al.*, 2001), rabbit (Chesne *et al.*, 2002), cat (Shin *et al.*, 2002), rat (Zhou *et al.*, 2003), white-tailed deer (Westhusin, 2003), mule (Woods *et al.*, 2003), horse (Galli *et al.*, 2003), banteng (Janssen *et al.*, 2004), African wildcat (Gomez *et al.*, 2004), dog (Lee *et al.*, 2005), ferret (Li *et al.*, 2006), wolf (Kim *et al.*, 2007), buffalo (Shi *et al.*, 2007), red deer (Berg *et al.*, 2007), and the camel (Wani *et al.*, 2010).

Efficiency of Cloning by Somatic Cell Nuclear Transfer

Typically, the success of obtaining a live birth after mammalian somatic nuclear transfer is low. In general, only 1–5% of

embryos transferred to surrogate mothers result in live offspring; however, since the first successful attempt, progress has been made that reflects improved technical skills and increasing knowledge of the underlying mechanisms (Niemann and Lucas-Hahn, 2012). For example, in cattle, efficiencies of 20–25% of live offspring are not uncommon for experienced commercial and research laboratories (Panarace *et al.*, 2007; Kues *et al.*, 2008). In pigs, although the average yield of live births per embryo transferred is only 3–5%, by transferring a large number of embryos per recipient sow, pregnancy rates can reach 80% with litter sizes averaging 6 cloned piglets; which, although lower than that of natural breeding (~10%), is a significant advance.

Interestingly, the *in vitro* development of SCNT embryos to the blastocyst stage is similar to that attained by *in vitro* fertilization (IVF). Also, after initial embryo transfer, a similar pregnancy rate was observed between SCNT- and IVF- or *in vivo*-derived bovine embryos (Kuroiwa *et al.*, 2004; Hill *et al.*, 2000; Heyman *et al.*, 2002). However, high incidences of pregnancy loss occur during the first trimester of gestation (Hill *et al.*, 2000; Heyman *et al.*, 2002; Zakhartchenko *et al.*, 2001). Also, late gestation losses are higher in SCNT pregnancies as compared with IVF- and *in vivo*-derived pregnancies (Heyman *et al.*, 2002). Fetal and placental abnormalities are often reported. Finally, high proportions of cloned offspring die soon after birth or require intensive care. The losses during gestation and in the early postnatal period are the main causes for the low overall efficiency of cloning by SCNT.

The majority of clones that survive to 6 months of age continue to develop normally and do not differ from naturally conceived animals in terms of blood and urine biochemistry (Chavatte-Palmer *et al.*, 2002), immune system (Lanza *et al.*, 2001), and reproductive parameters (Enright *et al.*, 2002) among others. Also, there is no difference in the composition of meat and milk from clones of cattle compared with their naturally produced counterparts of the same age, and similar results have been reported for cloned pigs (Archer *et al.*, 2003).

Some abnormalities manifested in animals derived from SCNT include 'Large Offspring Syndrome,' diabetes, pulmonary hypertension, viral infection, dystocia, kidney problems, leg malformations, pneumonia, heart defects, liver fibrosis, osteoporosis, joint defects, anemia, and placental abnormalities (Cibelli *et al.*, 2002). However, all the abnormalities seen in clones disappeared in the clone's offspring, leading to the conclusion that the abnormalities must be of epigenetic rather than genetic origin.

Applications of Somatic Cell Nuclear Transfer: Why Clone Animals?

Cloning by nuclear transfer has the potential to contribute substantially to animal agriculture, biotechnology, biomedicine, and the preservation of endangered species. The success of adult SCNT with almost all agriculturally important species confirms its usefulness for the clonal expansion of animals with superior genotypes (**Table 1**). Also, the ability to generate a complete individual from an *in vitro*-cultured cell provides an efficient means of making transgenic animals carrying complex genetic modifications. Furthermore, cloning can be used as a tool for aiding in the preservation of endangered species and has even been proposed as a means to rescue already-extinct ones. Finally, cloning offers a research model for studying the basic mechanisms of cell fate commitment, cell differentiation, and epigenetic reprogramming while providing new avenues for biomedical research and application.

Multiplication of Superior Animals

Cloning has the potential to allow the rapid dissemination of superior genetics. The dissemination of genetics with superior production potential directly to farmers and producers could dramatically increase animal production and reduce variability in production systems and products. Specific genotypes could be developed for different conditions and provided to farmers to match their particular environmental conditions and production systems. However, this would require that the efficiency of clone development closely matches that achieved by natural reproduction or currently used reproduction biotechnologies, such as artificial insemination and embryo transfer. Currently, embryos produced by SCNT cloning have a 10–50× lower developmental potential than naturally produced embryos, which limits its application and results in a high cost for cloned-animal production. Therefore, current agricultural applications of cloning are limited to animals of high economic value, such as those with elite genetics used for breeding purposes. Expanding the number of animals with highly desired genetics provides opportunities for increased embryo or semen production, increased breeding opportunities, and extended generational influence from clones of elite animals. Furthermore, a common application of cloning is the ability to recover the reproductive potential from animals that otherwise cannot produce offspring, such as the case with castrated animals, animals exposed to the stress of high athletic performance, and diseased animals. In the latter case, cloning can also offer a form of insurance against the natural or accidental death of an elite or prized animal.

The agricultural application of cloning technology is directly related to the safety of food products derived from these animals and their offspring (Rudenko *et al.*, 2007; Fox, 2008). Extensive studies from multiple regulatory agencies in several countries have concluded that meat and milk products from clones and their offspring are as safe for human consumption as those from naturally bred animals EFSA, 2010, 2012; FDA, 2008. Some concerns, especially with cloned individuals, are that the inefficient epigenetic reprogramming

Table 1 Somatic cell nuclear transfer in farm animals

inherent to current cloning methodologies can lead to abnormal epigenetic profiles, which, in turn, may alter meat and/or milk qualities. Also, animal welfare issues generated by the current methodologies, related to the increased incidence of pregnancy complications and need for additional early postnatal care of cloned animals, are of further concern. As these are reasonable concerns, more studies related to the influence of cloning on epigenetic status and the effects on food products derived from cloned animals are required.

Production of Genetically Modified Animals

Because cloning can be performed from *in vitro* cultured cells, it is possible to induce precise genetic modifications to the cells in culture, screen for correctly modified cells, and then use them to generate a transgenic animal. This ensures that all animals produced carry the genetic modification and that every cell type within the animal, including the germline, is transgenic. In spite of the inefficiencies of cloning by SCNT, this technique remains the most efficient one for generating transgenic farm animals. Furthermore, SCNT can be used for generating animals with precise genetic engineering, such as adding, deleting, or modifying specific genes at specific locations. Using this approach, cattle that lack the prion gene, responsible for bovine spongiform encephalopathy (mad cow disease), have been produced (Kuroiwa *et al.*, 2004). Targeted modifications have also been successfully achieved in sheep (McCreath *et al.*, 2000) and pigs (Lai *et al.*, 2002). Agricultural traits that have been considered for genetic modification are improved feed utilization, resistance to disease, reduction of animal waste, and diversification of agricultural products, i.e., providing new economic opportunities in rural areas and generation of new consumer products. A major hurdle to the advancement of transgenic technologies for agricultural applications are concerns about the cost and time associated with the regulatory processes necessary to bring products to market and potential consumer acceptance issues.

A higher economic incentive is associated with the production of genetically engineered animals for human medicine applications. Genetically engineered animals that can be used as bioreactors for the production of pharmaceuticals have been created. Many therapeutic proteins require production in animal cells, as mammalian cell culture bioreactors are expensive and inefficient. Genetically modified animals offer an opportunity for producing large quantities of animal proteins in their milk or blood and at a much lower cost.

Also, transgenic livestock, especially pigs, are being produced as biomedical research models for various human diseases, including Alzheimer's, diabetes, cystic fibrosis, and cardiovascular disease among others. The combination of precise genetic modifications and cloning by nuclear transplantation is being used to develop pigs whose cells, tissues, and/or organs will not be rejected if transplanted to humans. The cloning of pigs with genes from other species artificially introduced into their cells opened new doors in the field of medicine. These animals could provide an alternative source of organs for transplantation into humans (Nagashima *et al.*, 2012). For now, xenotransplantation – the transplantation of organs from a 'foreign' species – is not viable because different species are not immune compatible, causing organ rejection; however, a goal is that through genetic engineering, pigs with human-compatible organs could be produced.

Preservation of Endangered Species

Cloning using SCNT can be a useful tool for conserving exotic or endangered animal species and even for recovering extinct species. Cloning can be used to improve genetic diversity by recovering animals that would otherwise disappear from the population and by introducing genetics from animals that otherwise would not contribute to the genetic pool because of death and infertility associated with age or disease, even for animals that were too young to reproduce. For example, SCNT was used to clone the last surviving animal of the Enderby Island cattle breed (Wells *et al.*, 1998). Also, cloning could potentially be used to reintroduce specific genetic resources from captive to wild habitats, such as in cases where adults would not adapt well to wild conditions. A limitation of cloning endangered species is the source of oocytes and recipient animals to perform SCNT and produce offspring, respectively. A solution that has been proposed to solve this problem is the so-called interspecies SCNT, whereby oocytes from a species different to the donor cell are used for cloning and the resulting embryos can sometimes be gestated in a related species. Interspecies nuclear transfer was used to clone a Gaur (*Bos gaurus*) – an endangered species – by transferring Gaur somatic cells into cow oocytes and the embryos to a surrogate cow mother (Lanza *et al.*, 2000). A similar approach was used to clone the wild European Mouflon – an endangered breed of sheep – with tissue collected from dead animals (Loi *et al.*, 2001). So far, interspecies nuclear transfer has only been successful across subspecies. One of the potential limitations to the success of interspecies SCNT is nuclear–mitochondrial incompatibility, because mitochondria are provided by the oocyte and molecular incompatibility between reprogramming factors in the recipient cytoplast and the donor cell nuclear chromatin can occur (Beyhan *et al.*, 2007; Jiang *et al.*, 2011).

Furthermore, cloning by nuclear transplantation can be used to recover extinct species as long as genetic material from the species can be recovered. The feasibility of cloning a recently extinct species was recently demonstrated. The Pyrenean Ibex (*Capra pyrenaica pyrenaica*) is a wild goat species that went extinct in 2000. Investigators transferred cells from a specimen collected in 1999 into goat oocytes and implanted the embryos into surrogate goats in order to obtain a live clone (Folch *et al.*, 2009). Although this animal died a few hours later, it represented the first case in which an extinct species was brought back to life, even if for a few hours. Furthermore, the sequencing of the woolly mammoth nuclear genome from permafrost remains and the production of cloned animals from mouse cells cryopreserved without cryoprotectants suggest that revival of long-extinct species may be possible. However, for purposes of conservation biology, cloning is not generally accepted as an alternative to animal conservation, and there is an ongoing debate among scientists and experts on the role of cloning in animal conservation and rescue. At the very least, it seems appropriate to consider the cryobanking

of somatic cells from endangered species as insurance against possible losses in genetic diversity.

Cloning Animals: Methodological Approaches

A cloning program involves multiple components including: harvesting of recipient oocytes, isolation and preparation of a donor cell, nuclear transplantation (oocyte enucleation, nuclear transfer, and oocyte activation), culture of cloned embryos, transfer of embryos to recipients, pregnancy monitoring, delivery of cloned animals, and perinatal care of clones.

Many of these components are common to other animal reproductive biotechnologies such as IVF and embryo transfer. Each step of the process has crucial importance, as many factors can influence not only clone development but also the epigenetic status of the embryo, with potential consequences for later clone health.

Source of Biological Materials

Recipient cytoplasm

Only a few cell types in an organism have the potential to reprogram a somatic cell nucleus to allow for development of a whole individual. These include oocytes (the female gamete) and zygotes (the one-cell embryo). A metaphase recipient cytoplasm appears to be important for correct reprogramming of a somatic cell nucleus, in part because this allows for removal of the genetic materials without depleting all of the nuclear components. Meiotic metaphase II (MII) stage oocytes are the most commonly used recipient cytoplasm for nuclear transplantation, because it has proven to be capable of inducing reprogramming of transplanted nuclei from a variety of sources and species. Also, metaphase stage zygotes have been successful in producing live offspring after nuclear transfer in mice and cattle.

For most livestock species, oocytes are typically harvested from slaughterhouse-derived ovaries. This provides an abundant and economical source of gametes. Alternatively, oocytes can be collected from live animals by ultrasound-guided oocyte aspiration or by laparoscopy. In general, immature germinal vesicle oocytes (prophase I of meiotic division) are collected, which have to be *in vitro* matured before being used for SCNT. In cattle, sheep, and goats, *in vitro* oocyte maturation takes 22–24 h, and 42–44 h in pigs. *In vivo*-matured oocytes have also been used to produce cloned cows, pigs, and sheep, with typically better results than that when using *in vitro*-matured oocytes; however, the cost and extra labor associated with recovering matured gametes has resulted in most laboratories using *in vitro*-matured oocytes.

Donor cell

The donor cell has a key role in cloning and can be determinant of the success or failure of the procedure. In general, the efficiency of cloning is considered inversely proportional to the differentiation state of the somatic cell. Adult somatic cells are usually more difficult to reprogram than fetal cells, whereas embryonic cells often result in the greatest cloning efficiency. However, there is great variability between individual cell lines in determining the efficiency of clone animal production. This variability is associated not only with cells from different tissues and individuals but also between different subcultures of the same cell line. To date, the characteristics of a successful cell line for cloning by SCNT have not been identified.

Donor cells in the G0/G1 phases of the cell cycle are typically used for production of clones. Synchronization of the cell cycle in the G0 stage can be accomplished by reducing the concentration of serum in the culture medium or inducing contact inhibition by growing cells to confluence. Synchronization in the G1 stage can be achieved by first selecting cells in mitosis and then allowing those cells a short time (1 h) to complete mitosis and enter the G1 stage. Also, mitotic cells have been used to produce mouse clones, although this is a less-common approach in farm animals. Cells from different tissue types may be used as donors in cloning. Some of the cell types that have been successfully used include mammary gland epithelial cells, cumulus cells, oviductal cells, granulosa cells, hepatocytes, endometrium cells, myocytes, Sertoli cells, T and B lymphocytes, neurons, and fibroblasts (Brem and Kühholzer, 2002; Miyoshi *et al.*, 2003; Campbell *et al.*, 2007). Easy accessibility and ability of the cells to grow *in vitro* are characteristics that facilitate cloning programs. Skin-derived fibroblasts are one of the most commonly used cell types for SCNT cloning in livestock species, given that they can be easily obtained from a small skin biopsy and are easily cultured.

Oocyte Enucleation and Nuclear Transfer

Three main approaches are most commonly used in livestock nuclear transplantation. These include traditional nuclear transfer, hand-made cloning (HMC), and zona-free nuclear transplantation. Traditional nuclear transfer involves enucleation of the oocyte by aspirating the metaphase II plate with a sharp micropipette in a zona pellucida (ZP)-intact oocyte in order to remove the chromosomes, then transferring a whole donor somatic cell into the perivitelline space of the oocyte, and finally fusing together the donor cell to the oocyte recipient and thus delivering the somatic cell nucleus into the oocyte cytoplasm. HMC consists of oocyte halving with a sharp micro scalpel and fusing the two nonnucleated oocyte halves with a somatic cell. Finally, zona-free nuclear transfer involves removing the ZP of the oocyte, enucleation with a blunt-end needle, and fusion of the enucleated oocyte to a somatic cell.

Traditional nuclear transfer

The traditional method for nuclear transplantation is without a doubt the most commonly used technique for the production of cloned animals. This technique makes intensive use of micromanipulation and thus requires highly specialized equipment and personnel. Oocyte enucleation is performed under a high-power microscope (200–400 × magnification) using a sharp glass micropipette to aspirate the metaphase plate, thus removing the recipient cell chromosomes leaving only cytoplasm. Typically, the first polar body (PB) is also removed by aspiration. The manipulations are assisted by

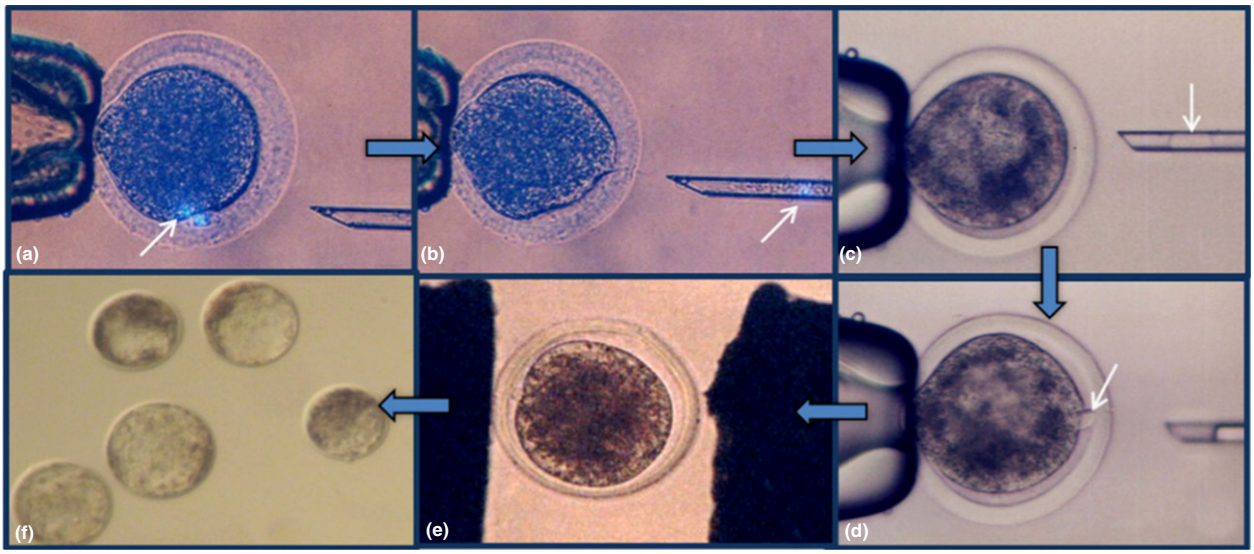

Figure 2 Traditional nuclear transfer. (a) Oocyte (arrow: DNA stained with Hoechst 33342); (b) Enucleation (arrow: aspirated metaphase plate); (c) Donor cell inside the transfer micropipette (arrow); (d) Nuclear transfer (arrow: donor cell in perivitelline space); (e) Fusion; and (f) Blastocysts produced by traditional nuclear transfer.

holding the oocyte in place using another micropipette. As oocytes from most farm animals are dark, because of high lipid content, the metaphase plate cannot be directly visualized. Therefore, visualization of the metaphase plate can be aided by DNA staining using a live fluorescent dye such as Hoechst 33342. As staining and visualization under UV light can damage oocytes, blind enucleation can also be used by removing the cytoplasmic material in proximity to the PB, although this is not always successful and residual DNA may be left behind.

After oocyte enucleation, a donor cell is transferred into the perivitelline space of the oocyte (between the oocyte membrane and the ZP), also through micromanipulation. For transfer, the same hole in the ZP created during enucleation can be used; however, it is usually more efficient to make a new perforation of the ZP in order to transfer the somatic cell. Finally, the nucleus of the donor cell is delivered into the oocyte cytoplasm by fusing the two cells together. This is usually achieved by applying a short high-voltage electric direct current (DC) pulse perpendicular to the apposed cell membranes. This electric pulse creates holes in the cell membranes of the donor cell and recipient cytoplasm and as the membranes are repaired they fuse together at their point of contact. Once fused, the oocyte cytoplasm containing the nucleus of the donor cell is called a reconstructed embryo.

A modification to traditional cloning that is more common in rodents, but that has also been successfully applied to livestock species, involves intracytoplasmic injection of the somatic cell nucleus rather than fusion of oocyte and somatic cell. For injection into the oocyte cytoplasm, a piezoelectric device is normally used. Piezo-driven injection of the donor nucleus has been successfully accomplished in oocytes from horses, cattle, swine, mice, and rabbits (Onishi *et al.*, 2000; Choi *et al.*, 2002; Gao *et al.*, 2004; Du *et al.*, 2009). Other modifications to the enucleation and transfer procedures exist, such as using chemicals to facilitate oocyte enucleation (e.g., demecolcine) or using Sendai virus to induce cell–oocyte fusion Figure 2.

Hand-made cloning

The cloning technique called HMC (Figure 3) is considered easier to perform and requires less equipment when compared with other techniques (Vajta *et al.*, 2005), thus reducing the initial investment for implementing a cloning program.

For HMC, the ZP of the oocyte is removed by enzymatic treatment (typically using pronase). Then, zona-free oocytes are manually bisected using an ultrasharp blade. This step is typically performed under a low-power stereoscope (20–60 × magnification) and does not require micromanipulation equipment. Hemioocytes are then stained with a fluorescent DNA stain (Hoechst 33342), screened for nuclear material under UV light, and nonnucleated ones selected. For embryo reconstruction, two nonnucleated hemioocytes (hemicytoplasts) and one donor cell are fused together by electrical stimulation, achieving approximately 100–120% of the original oocyte cytoplasmic volume. Phytohemagglutinin (PHA) is commonly used to facilitate adherence of hemicytoplasts and somatic cells. After treatment of hemicytoplasts with PHA, the somatic cell is 'glued' to the surface of the cytoplast, which facilitates cell alignment and fusion.

Embryos produced by HMC or any other technology that involves removal of the ZP need to be cultured individually in a conical container, in order to prevent embryo aggregation and cell dispersion, respectively. Normally, HMC embryos are cultured in microwells using the well-of-the-well (WOW) system, which consists of small depressions or microwells on the surface of a plastic embryo culture dish (Vajta *et al.*, 2000).

Zona-free nuclear transplantation

This technique combines concepts of traditional cloning techniques and HMC (Figure 4; Oback *et al.*, 2003). As in HMC, the ZP of the oocyte is removed, which simplifies the

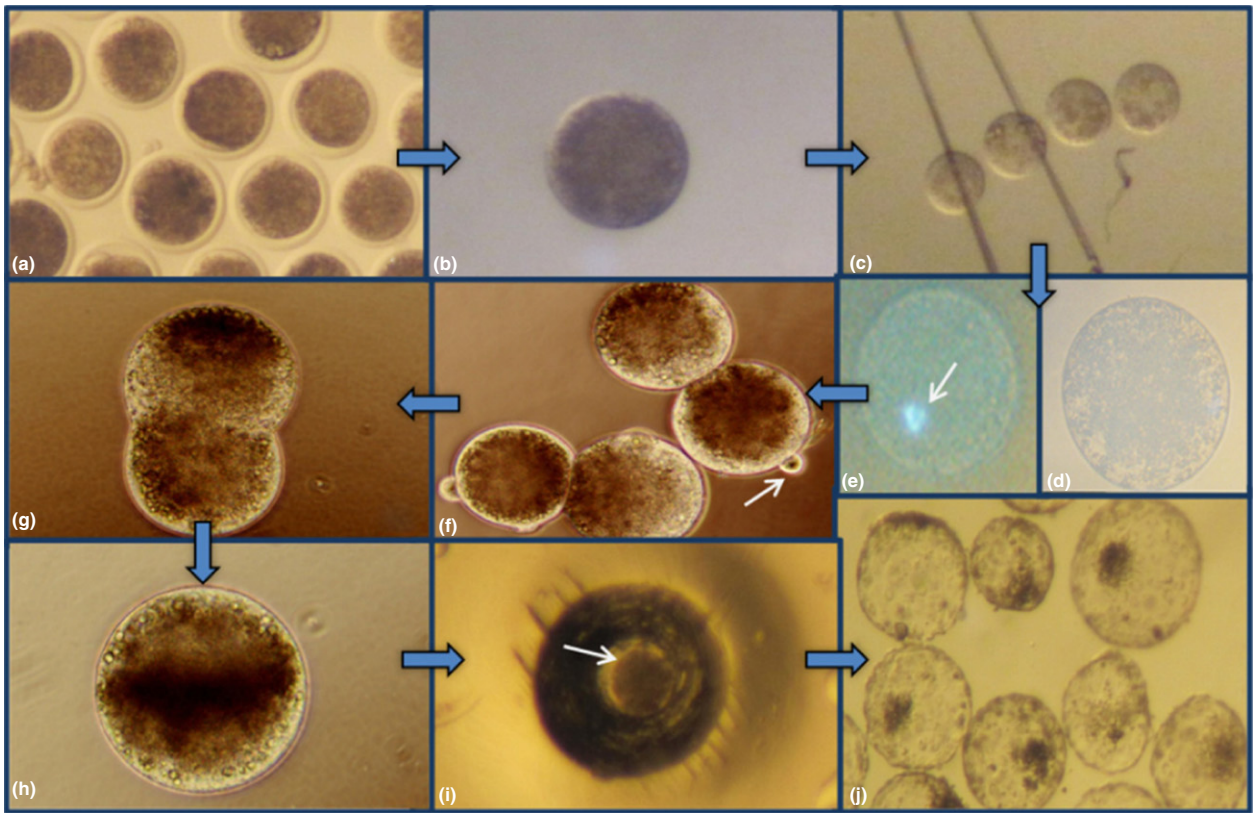

Figure 3 Hand-made cloning. (a) Oocytes; (b) Oocyte without zona pellucida; (c) Hand-bisected hemioocytes; (d) Hemioocyte without DNA; (e) Hemioocyte with DNA (arrow indicates DNA – this hemioocyte is discarded); (f) Donor cell (arrow) attached to two hemicytoplasts; (g) Fusion; (h) Reconstructed embryo; (i) Reconstructed embryo (arrow) inside well-of-the-well; and (j) Blastocysts produced by hand-made cloning.

procedures for enucleation and nuclear transfer and requires less technical expertise and the production of more basic micromanipulation tools. After removal of the ZP, the oocyte is supported in a holding pipette, and with the aid of a blunt enucleation pipette, a portion of the oocyte cytoplasm where the PB is localized is aspirated. For reconstruction and nuclear transfer, one enucleated oocyte is quickly exposed to PHA and then attached to one donor cell. Following attachment, the cell and cytoplast are electrofused. After assessment of the fusion outcome, the reconstructed embryos are activated and individually cultured in the WOW system.

Oocyte Activation

The natural activation of an embryo, and consequently the beginning of the first cleavage divisions, are caused by oscillation of intracellular calcium triggered by the sperm. Because somatic cells do not carry this sperm capacity, artificial activation of SCNT embryos is absolutely required. Numerous procedures have been developed to activate mammalian oocytes (Machaty, 2006). As calcium is a key regulator of oocyte activation, several approaches to artificial oocyte activation rely on inducing single or repetitive rises in calcium levels. In livestock, oocyte activation can be achieved through a variety of protocols (Machaty, 2006). The most prevalent protocols induce a single intracellular increase in calcium, which can be achieved by physical or chemical means (Alberio *et al.*, 2001). Electrical stimulation by administration of DC pulses in the presence of exogenous calcium induces calcium influx through pores formed in the plasma membrane (Fissore and Robl, 1994). This activation method was successfully used in cloning the first sheep and goats (Baguisi *et al.*, 1999; Wilmut *et al.*, 1997). The most commonly used activation protocols in bovine SCNT utilize a calcium ionophore, such as A23187 or Ionomycin (Machaty, 2006). Ionophores allow passive diffusion of calcium though the plasma membrane and thus induce a single large increase in calcium (Nakada and Mizuno, 1998). Because a single calcium surge is not enough to completely activate the cell cycle and initiate embryonic development, the calcium stimulus is supplemented with chemicals that help to regulate the cell cycle (Alberio *et al.*, 2001). Among them, DMAP, a kinase inhibitor, can be used after ionomycin treatment to induce high rates of oocyte activation (Susko-Parrish *et al.*, 1994). This activation treatment was used in production of the first cloned calves (Cibelli *et al.*, 1998) and is widely used today. Another possible way to regulate the cell cycle is by using protein synthesis inhibitors. Cycloheximide is a protein synthesis inhibitor that has been used to activate cloned bovine embryos (Zakhartchenko *et al.*, 1999). Other methods to induce repetitive calcium rises include injection of sperm extracts or recombinant sperm factors.

In vitro Culture and Embryo Transfer

After the activation period, embryos are cultured with *in vitro* systems that mimic the oviductal or uterine environments. The success rates of *in vitro* culture are variable among species. Culture systems for bovine embryos are well advanced and allow routine production of 30–45% blastocysts from *in vitro*-fertilized bovine oocytes isolated from abattoir ovaries (Gandhi *et al.*, 2000). In the case of cattle, the reconstructed embryos can be cultured *in vitro* to the morula/blastocyst stage (5–7 days) to assess the initial developmental competence before transfer into a foster mother. In contrast, the requirements for proper growth of embryos in other species are not well established and *in vitro* embryo culture is less efficient. In pigs and goats, although it is possible to obtain blastocysts cultured *in vitro*, the pregnancy rates achieved with these embryos are low. With small ruminants, the best results are obtained when the embryos are cultured for shorter periods such as 1–2 days. In contrast, porcine reconstructed embryos are normally transferred immediately after activation (Petersen *et al.*, 2008).

The timing of *in vitro* culture will determine which stage the clones' embryos will be transferred. Typically, bovine embryos are transferred at the morula or blastocyst stage directly into the uterus of recipient females with their estrous cycle synchronized to the age of the embryo. In cattle, the transfer is performed using the same nonsurgical techniques developed for regular embryo transfer. In small ruminants and pigs, the reconstructed embryos are often transferred directly into the oviducts of recipient females by laparoscopic or surgical methods.

Pregnancies from cloned embryos need to be closely monitored, given the higher incidence of potential complications. This typically involves regular ultrasound examinations to check fetal viability and sizes of the placenta and umbilical cord, among other parameters. Delivery of clones must also be closely monitored and planned, usually requiring cesarean section. Finally, cloned animals often require extreme perinatal cares such as oxygen supplementation, respiratory assistance, blood glucose normalization, among other considerations. Once a cloned offspring passes the neonatal period, they do not typically need any more attention than that given to naturally reproduced animals.

Conclusion

The ability to produce offspring from cultured somatic cells allows the rapid propagation of superior genotypes, genetic improvement of domestic species, the production of biopharmaceuticals and nutraceuticals by cloned animals, organs for xenotransplantation, genetically engineered animal models of human diseases, and preservation of endangered species. Although these applications for SCNT are far reaching, its broad implementation has been hindered by low efficiency.

Although advances in recent decades have allowed improvement in the preimplantation development of cloned embryos, their full-term developmental potential remains low. High rates of early pregnancy loss are often observed along with an increased incidence of abortions in late pregnancy. Moreover, high mortality rates of offspring from cloned embryos are reported, which makes the overall efficiency of SCNT range between 1 and 5%.

The inefficiencies of cloning negatively affect the economic and commercial viability of SCNT. However, a wealth of

knowledge has been generated in an attempt to solve these problems and many fields of science are emerging and consolidating as a result, especially areas that try to understand the mechanisms of epigenetic reprogramming and specific physiological aspects of pregnancy and neonatal development.

Regulatory agencies around the world have agreed that food from cloned animals and their offspring is safe for human consumption. However, SCNT raises new questions about the ethical and moral status of animals and their welfare, which have caused controversial discussions around the world. As technical refinements and increased knowledge of the mechanisms underlying nuclear reprogramming continue to develop, improvements in the success rate of cloning and decreases in the potential for adverse events should occur. This will result in lowered costs for cloned animal production, increased acceptability for products derived from clones and their offspring, and a more widespread application of this technology in commercial enterprises.

Cloning: Plants – Micropropagation/Tissue Culture

PE Read, University of Nebraska-Lincoln, Lincoln, NE, USA
JE Preece, University of California, Davis, CA, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Acclimatization The process of hardening or conditioning micropropagated plants so that they will survive in the greenhouse or field.

Adult plant A plant that is physiologically mature enough to flower under normal inductive conditions. Compare with juvenile plant.

Adventitious bud, root, or shoot An organ that forms at an 'unexpected' location, such as roots on a stem or leaf, or shoots on a root or leaf.

Callus Unorganized group of cells that forms on plant parts or explants as a result of wounding or application of plant growth regulators, such as auxins and cytokinins.

Clone A population of organisms (plants) that is asexually derived and can be traced back to an original individual.

Dedifferentiation When differentiated (specialized) cells return to the meristematic condition often to replace a missing or wounded part, such as a root or shoot. This is a typical wound healing response for plants, and is utilized in vegetative plant propagation, such as rooting cuttings and microcuttings, grafting, and other vegetative propagation techniques.

Differentiation When cells become more specialized than the meristematic condition. Meristematic cells have one function: division (mitosis). All other cell types differentiate from cells produced in meristems via cell division.

Embryogenesis Formation of embryo-like structures *in vitro* or in planta, derived directly from explant cells or indirectly from callus cells.

Ex vitro The environment outside of the vessels containing plant tissue cultures. Typically the greenhouse and field are referred to as *ex vitro* environments for micropropagated plants.

Explant The plant tissue or organ that is removed from the stock plant and is first placed *in vitro* during the micropropagation process. Subcultured shoots are also typically called explants.

In vitro The vessels containing plant tissue cultures. Although originally meaning 'in glass,' now all micropropagation is said to be *in vitro*, regardless of the material used for the container.

Juvenile plant A plant that is in a vegetative state and incapable of responding to flower induction stimuli that would usually lead to flowering in an adult plant (see adult plant). Cuttings root more readily and micropropagation is facilitated if juvenile stock plants are used.

Laminar flow hood An enclosed, protected chamber (transfer chamber) that passes air through a specialized filter to create an atmosphere free from contaminants where micropropagation transfers take place using sterile techniques.

Meristem Tissue composed of dividing cells. Primary meristems are shoot and root tips, secondary meristems are the vascular and cork cambia, and adventitious meristems form at unexpected locations and will give rise to roots or shoots; meristem culture is employed to produce disease-free stock plants.

Organogenesis Initiation of adventitious organs, such as roots or shoots.

Somaclonal variation When plants produced *in vitro* exhibit phenotypic differences because of mutation, epigenetic, chimera separation and other reasons. Adventitiously produced plants, especially from callus have an increased likelihood of showing somaclonal variation, whereas the clonal uniformity is maintained by utilizing an axillary shoot multiplication system.

Totipotency Theory that all living cells contain all the genetic information necessary to develop into a complete intact organism.

Introduction

In 1902, Gottlieb Haberlandt broached the subject of plant tissue culture and micropropagation in his seminal publication (Haberlandt, 1902) in which he endeavored to explore totipotency and morphogenesis in plants. His efforts were largely unsuccessful, primarily related to a lack of knowledge about the requisite medium components. Subsequently, plant scientists vigorously pursued definition of conditions necessary to successfully produce viable cell, tissue, and organ cultures (Read, 1992). In the more than a century that has elapsed, there have been thousands of reports related to attempts to refine media, environmental conditions (both *in vitro* and *ex vitro*), and other parameters conducive to successful *in vitro* culture resulting in micropropagation success and commercialization. Murashige produced an excellent review in which he presents detailed descriptions of the stages of the process and constituents of media successfully employed for plant micropropagation (Murashige, 1974). At that time he was able to list information related to micropropagation of more than 100 genera from more than 50 plant families. That number has expanded greatly to include most food, fiber, ornamental, medicinal, and other important plants.

A wide range of factors are required for successful micropropagation, including the source of explant material (the 'stock plant,' donor plant, or mother plant), environmental conditions under which the stock plant is grown, the culture environment (both in the culture vessel and the culture's

external environment, constituents of the *in vitro* medium, and subsequent procedures employed for multiplication, rooting, and acclimatization).

Why did not Haberlandt's experiments yield successful micropropagated plants? As often is the case in science, requirements for success were yet to be discovered. A major step was accomplished when Went (1929, 1934a,b) reported on the root-forming substance, initially referred to as rhizocaline, later identified as indoleacetic acid (IAA) or auxin (Went, 1934a,b; Thimann and Went, 1934). Subsequently, analogs of IAA, indolebutyric acid (IBA) and naphthaleneacetic acid (NAA), although not endogenous, were discovered to have even stronger abilities to stimulate root formation (Zimmerman and Wilcoxon, 1935, Thimann, 1935) than IAA. Numerous reports of research employing auxin followed in the next decades. Nobecourt and Gautheret, working in different laboratories in France with carrot cultures, demonstrated successful callus growth and Phillip White in the USA reported successful culture of an organ (tomato roots, White, 1963). Previously, Knudson (1922) demonstrated that a defined medium could be employed to germinate and culture seeds of tropical orchids. His Knudson C medium is still commonly used commercially for seed germination and tissue culture of orchids (Knudson, 1951).

Despite the success of Gautheret and White in repeated cultures of tomato root callus – indeed they could culture such callus in a defined medium almost indefinitely – regeneration of intact plants from plant tissue cultures remained essentially impossible. It was not until Miller and Skoog's laboratory group at the University of Wisconsin isolated kinetin from autoclaved herring sperm and described the action of this compound in cultures of tobacco pith tissues, that plant regeneration *in vitro* became a reality (Skoog and Tsui, 1948; Skoog and Miller, 1957). They referred to the class of compounds to which kinetin belongs as cytokinins (cyto = cell, kinesis = division, hence compounds that stimulate cell division). Skoog and Miller (1957) further described the relationship of ratios of auxin to cytokinin in the culture medium; they determined that when auxin predominates in the medium, root formation is stimulated, when cytokinin is in excess, bud and shoot formation occurs. If neither auxin nor cytokinin activity predominate, only callus is formed.

At approximately the same point in the history of plant tissue culture, Morel and Martin (1952) showed that by culturing excised meristems of dahlia, endogenous viruses that cause serious diseases could be eliminated. Morel later reported that similar results could be attained with meristem culture of *Cymbidium* orchids (1960). As a consequence of his research with meristem culture of orchids, he discovered that following initiation of meristem culture, plants could be multiplied *in vitro*, leading to a clonal propagation system that is still practiced today (Morel, 1964). In 1967, Marston and Voraurai reviewed the literature on clonal propagation of orchids by utilization of meristem culture techniques.

The foregoing noted accomplishments ultimately led to the landmark paper by Murashige and Skoog that revolutionized plant tissue culture (Murashige and Skoog, 1962). The medium formulation developed by their work formed the basis for thousands of studies in which the now-famous Murashige and Skoog (MS) medium was employed. Indeed a preponderance of medium formulations used for micropropagation research and commercial multiplication of elite clones of a myriad of plant species are based on the MS medium.

It would be nearly impossible to list all of the researchers and plant species and genotypes that have been reported since the Murashige review, but a few of the classic examples should be noted. Ball's work with sterile cultures reported in 1946 helped lay the foundation for the work that followed (Ball, 1946), including that already noted for Murashige, Skoog, Miller, and Morel. Nitsch and Nitsch were contemporaries who conducted numerous tissue culture experiments and provided other medium formulations employed in later research (Nitsch and Nitsch, 1956). They even reported on flower induction of *Plumbago* stem segments cultured *in vitro* (Nitsch and Nitsch, 1967). Reinert's work with embryogenesis (Reinert, 1959; Reinert and Mohr, 1967; Reinert *et al.*, 1967) and that of Steward (Steward *et al.*, 1958) contributed greatly to the fields of embryogenesis, suspension culture, and medium composition. Many other researchers also worked with cell suspensions, liquid culture, and medium constituents named after them when used in later research, for example, Gamborg's Medium (Gamborg *et al.*, 1968; Vasil *et al.*, 1964; Norstog, 1965).

As research with plant tissue cultures progressed, especially with callus suspension and embryogenic cultures, it became clear that aberrations would frequently occur. The resulting plants often would be different genetically and phenotypically from the plant from which the explant was taken. This was readily apparent when asparagus *Asparagus officinalis*, tobacco *Nicotiana tabacum*, carnation *Dianthus caryophyllus*, and other plants were regenerated from callus or cell suspension cultures (Wilmar and Hellendoorn, 1968; Murashige and Nakano, 1966). Sometimes such changes could be advantageous, for example, changes in scented geranium (Skirvin and Janick, 1976). Shepard *et al.* (1980) demonstrated wide-ranging variability in 'Russett Burbank' potato regenerated from leaf protoplasts. Larkin and Skowcroft (1981) coined the term 'somaclonal variation' and espoused the value of somaclonal variation for plant improvement. Likewise, Cocking's (Cocking, 1960) demonstration of the potential of culturing plant protoplasts has also exhibited promise for plant regeneration, parasexual hybridization, and plant improvement, but also will not be addressed in this article. Later, Grosser (1994) described methodology for protoplast isolation and somatic hybridization in citrus, also with encouraging results. Murashige (1974) commented that off-type plants commonly occur when plants are adventitiously regenerated from callus and stated "The frequency of genetically aberrant plants can be reduced considerably, even avoided entirely, if the plant multiplication can be achieved through an enhancement of axillary shoot formation." The authors therefore have chosen to restrict our discussion to use of techniques that to a high degree retain the genetic and phenotypic identity of the plant being cloned via micropropagation.

Murashige's review suggested three stages of micropropagation: Stage I, Establishment of the aseptic culture, Stage II, Multiplication of propagule, and Stage III, Preparation for re-establishment of plants in soil (Murashige, 1974). Subsequently, general micropropagation practice, both for

research and commercial production, has been to consider five stages: (0) stock plants, (I) establishment, (II) multiplication, (III) pretransplant, and (IV) transplant (Anderson, 1980; Murashige, 1978). These four stages have been used for the discussion preceded by Stage 0, that is, the Stock Plant stage.

Stage 0: Stock Plants

The plant from which the explant intended for micropropagation is taken may be referred to as the stock plant, donor plant, or mother plant. The overall characteristics of this stock plant are critical to the success of the micropropagation process (Read, 1990; Read, 1992). Freedom from endogenous pathogens such as viruses, bacteria, and fungi is essential because micropropagation of a virus-infected plant is simply a way to produce many more unwanted virused plants. Hence, it is important and obvious that the propagator must start with a healthy plant.

Explant Selection

Many researchers have shown that explants taken from juvenile stock plants or from juvenile parts of the stock plant perform better *in vitro*; this response is similar to the better rooting of cuttings taken from juvenile plants when compared with cuttings from mature plants such as *Hedera helix* (Hackett, 1983). Sources of juvenile material are depicted schematically by Preece (2008) in which he notes the 'cone of juvenility,' epicormic shoots, stump sprouts, and root suckers, among others. Similarly, it has been demonstrated that explants secured from tissue culture-derived stock plants frequently respond better *in vitro* than explants taken from greenhouse or field-grown stock plants. This was shown for azalea (Economou and Read, 1986) and strawberry (Liu and Sanford, 1988). Furthermore, when location on the stock plant is considered, for example, apical bud versus lateral bud, the best results vary with species: lateral buds were superior for deciduous azalea (Economou and Read, 1986), but apical explants responded better for *Fagus sylvatica* (Vanderschaege and Debergh, 1988). Genotypic differences have been widely reported to lead to varying *in vitro* performance, for example, *Pelargonium* shoot tips and organogenesis in sweet potato (Pillai and Hildebrandt, 1968a,b; Gunckel *et al.*, 1972). With a relatively easy to micropropagate species such as petunia, shoot-forming ability from leaf segment explants varied by as much as fivefold, depending on cultivar (Read, 1990).

Nutrition of the Stock Plant

The classic work of Kraus and Kraybill (1918) demonstrated that nutrition of tomato stock plants had a marked effect on rooting of cuttings. The authors in their research found similar impact on tomato leaf segments cultured *in vitro* (Read *et al.*, 1979). When explants were taken from stock plants receiving high amounts of nitrogen, fewer shoots were produced *in vitro* when compared with explants from stock plants receiving a lower, but adequate for normal growth, amount of nitrogen fertilizer. They also found that nitrogen and potassium levels provided to hydroponically grown *Salix* stock plants exerted a strong influence on organogenesis of *in vitro* cultures of explants excised from such stock plants (Read *et al.*, 1982, 1983). In this case, however, nutrition of the stock plant was insufficient to overcome poor performance *in vitro* of inherently recalcitrant genotypes. It seems apparent that not only adequate nutrition of the stock plant is important to tissue culture success, but excess nutrients will not substitute for inadequate nutrition in the culture medium.

Light Level, Quality, and Photoperiod Stock Plant Effects

Conflicting reports are found in the literature regarding the effect on explant performance when stock plants receive high or low levels of light or no light at all. Dunwell and Perry (1973) found enhanced haploid plantlet production from anthers taken from stock plants grown under high photon flux, whereas Hughes *et al.* (1978) obtained higher protoplast yield if the donor plants were grown under low light. A complicating factor was that in both cases the stock plants were grown under short days. Some plants are sensitive to photoperiod, so their normal physiological responses may parallel *in vitro* performance. It is possible that rooting, as Mes (1951) proposed, is reduced under high light levels due to a reduction in auxin content, whereas the enhanced shoot production noted by Yu and Meredith (1986) for shoot tips of shaded grape stock plants may have been related to high cytokinin content because filtered light may increase the red light component (Yu and Meredith, 1986; Economou and Read, 1986; Read, 1990). Petunia stock plants that received 30 min of light rich in red light at the end of each growing day produced explants that proliferated more shoots than explants receiving far-red light at the end of the day. This suggests a possible phytochrome effect, because red light followed by far-red reduced the shoot-stimulating effect of red light (Read *et al.*, 1978). Similarly, petunia leaf segments cultured on cytokinin-free medium provided with 15 min of light at the end of the day produced more shoots than explants taken from cultures receiving far-red light (Economou and Read, 1987).

Stock Plant Temperature Effects

The temperature under which the stock plant has been grown may have a profound impact on explant *in vitro* performance, although this topic has only been sporadically studied. Heide (1965) found an interaction between temperature and auxin and cytokinin levels when culturing begonia leaf segments. Stimart and Ascher (1981) reported that duration of storage at 4 °C influenced bulblet formation from lily bulb scale segments and the authors found differing responses to storage temperature and time in storage when hyacinth bulb scale segments were cultured *in vitro* (Read *et al.*, 1984; Ko, 1986). This was in contrast to the work of Pierik and Ruibing (1973) who suggested that bulblet production was not significantly affected by duration of storage. A stimulation of adventitious bud and root formation was affected when leaf discs of *Streptocarpus* were excised from stock plants subjected to a cold period (12 °C) before leaf harvest (Appelgren and Heide, 1972). In general, however, limited research has been pursued

with regard to stock plant temperature, suggesting that this could be a field for further research.

Plant Growth Regulator Treatment of the Stock Plant

Inclusion of hormone-like growth regulators in the culture medium has been extensively investigated and is discussed in the Section 'Stage I: Establishment.' Treatment of the stock plant to 'program' the explant tissue before culture has proved to be an approach that can be helpful in micropropagation. This approach was pursued by DeLanghe and DeBruijne (1976) with tomato leaf segment culture. In their research a growth retardant, chlormequat chloride, was sprayed onto the stock plants at 2000 ppm, leading to an increase in shoot proliferation. This response was repeated in our laboratory with tomato and with daminozide (another growth retardant) applied to dahlia stock plants (Read *et al.*, 1979). Similarly spraying petunia stock plants with daminozide led to greater shoot proliferation from leaf segments cultured *in vitro* than from leaf segments from stock plants sprayed with water (Economou and Read, 1980)

Preculture Treatment of Explants

Growth-regulating chemical treatments to the explants themselves before culture has been hypothesized as an approach that could obviate the need for inclusion of the compound in the medium. Dipping petunia leaf segments into cytokinins such as benzyladenine (BA) and culturing on cytokinin-free medium led to equivalent shoot formation to that of cultures containing BA in the medium (Economou and Read, 1982). Treatment of the explant offers some advantages over placement of the growth regulator in the medium and often has resulted in better quality plants than the traditional method of incorporating cytokinins in the medium.

Shoot Forcing

Forcing solutions

Woody plant tissue culture has often proved to be difficult, primarily because cells or tissues of woody plants are cellulosic and lignified. As a result, the period of time when soft, non-lignified shoots can be obtained often is limited to a brief period in the spring when the first flush of growth occurs. Employing a solution such as those used commercially for extending the keeping quality and longevity of cut flowers, such as roses, chrysanthemums, and carnations, has enabled relatively clean, soft tissue to be obtained for explant use. The solution used mimics the one used for cut flowers: 58.4 μM sucrose (2% solution) and 592 μM 8-hydroxyquinoline citrate (200 ppm). Woody stems are cut from the stock plants and the cut bases placed into vessels containing the forcing solution (**Figure 1**). A fresh cut is made to remove 1–2 mm from the base of the stem and the solution replaced every 2–3 days. Delivery of plant growth-regulating chemicals via the xylem uptake from the forcing solution may be accomplished by inclusion in the forcing solution (Read *et al.*, 1984, 1986). Buds from dormant woody stems have been stimulated to emerge and elongate in spite of an endodormant condition by preforcing treatments and by inclusion of gibberellic acid (GA_3) in the forcing solution. A preforcing treatment with 15% bleach solution hastened bud break and promoted shoot elongation (Yang and Read, 1992), whereas GA_3 at 10 mg l^{-1} in the forcing solution consistently led to earlier bud break and shoot elongation (Yang and Read, 1989, 1997). In addition, including BA in the forcing solution increased the number and size of shoots formed *in vitro*, but had minimal effects on days to bud break. Inclusion of auxins, such as IAA and NAA, in the forcing solution delayed bud break, but shoots produced from such forcing treatments could be useful for rooting as softwood cuttings. Because silver thiosulfate (STS) became a common treatment for enhancing cut flower longevity, studies with STS in the forcing solution to determine potential for improving bud break were initiated. It was found that 5 μM STS in the forcing solution reduced time to bud break and increased both percent bud break and shoot elongation for several woody species (Hamooh and Read, 2000).

Forcing large stem sections

An alternative approach for obtaining soft growth for explants was reported by Vieitez *et al.* (1994) when they forced branch segments of mature *Quercus robur* to obtain explants for micropropagation. This technique takes advantage of the production of epicormic shoots and can exploit the juvenile portion of a plant for propagation purposes and has been refined and exploited by Preece and colleagues (**Figure 1**). They have successfully forced epicormic shoots of numerous deciduous woody species, including maple, black walnut, hibiscus, and others, providing quality explants for micropropagation (Van Sambeek *et al.*, 1997a,b; Henry and Preece, 1997a,b; Ledbetter and Preece, 2003). The technology for forced epicormic shoots from mature woody stems is summarized in Preece and Read (2003) and Preece (2008) and descriptions of environmental and medium considerations were presented by Aftab *et al.* (2005).

Serial grafting

Stems of a number of woody species have been 'rejuvenated' by repeatedly grafting mature stems onto juvenile rootstocks. The process often needs to be repeated several times, depending on species/genotype, in order for juvenility to be re-established (Debergh and Maene, 1985; Bonga and Von Aderkas, 1992). Franclet (1987) and Boulay (1987) have reported extensively on this process, especially with conifers. Using small shoot tips as scions enhanced rejuvenation in avocado when conducted *in vitro* (Pliego-Alfaro and Murashige, 1987) and was studied for juvenile and mature clones of *Sequoiadendron giganteum* by Monteuius *et al.* (1987).

Stage I: Establishment

The primary objective of Stage I is to successfully introduce the explant onto the medium by using clean explants and aseptic techniques (**Figure 2**). Because the objective of micropropagation is to produce a population of uniform genotype (cloning, asexual propagation), this article focuses on use of existing meristems. Although much research has

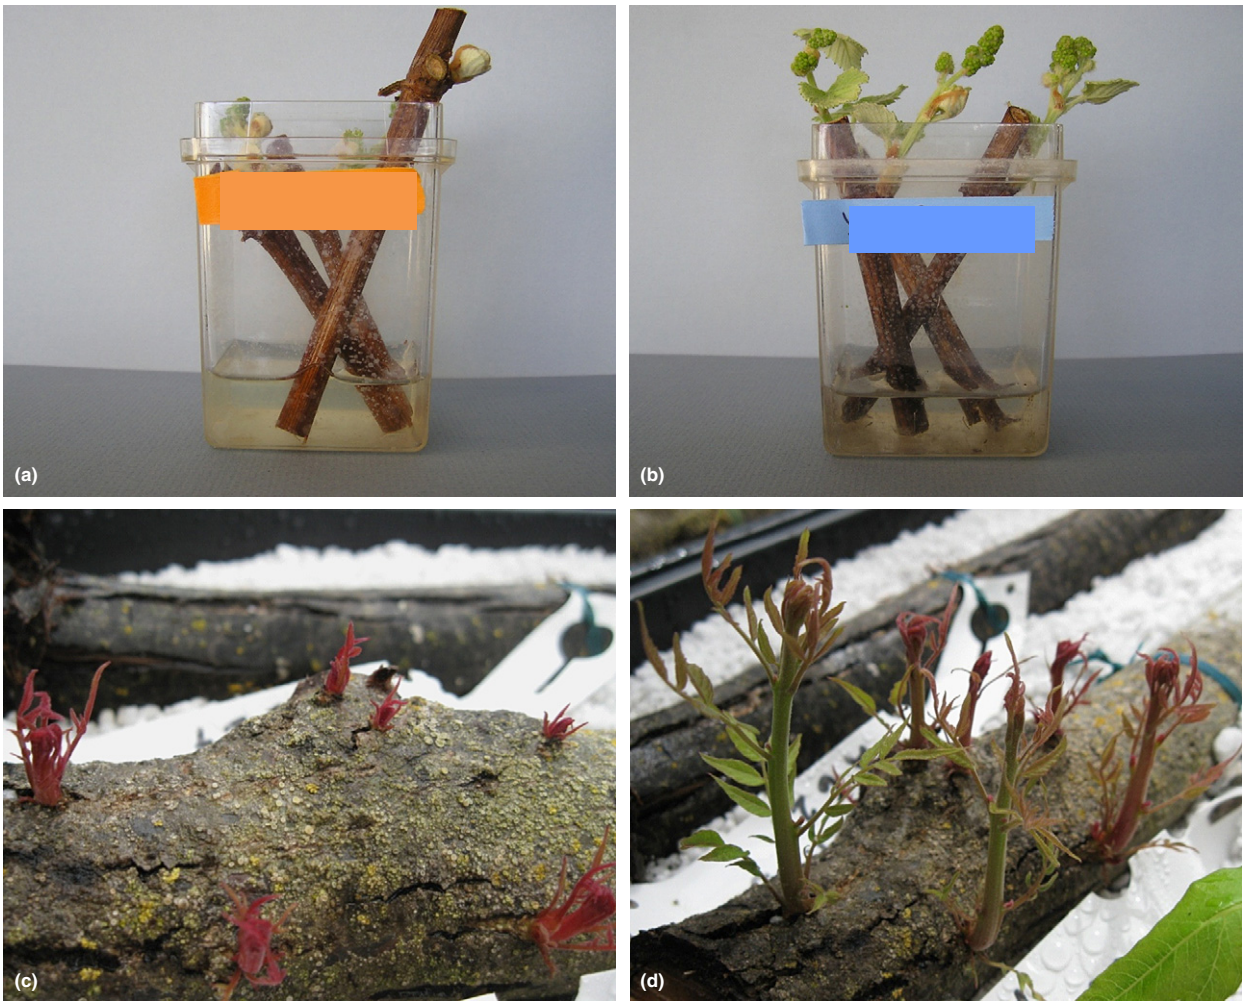

Figure 1 (a) and (b) Shoot forcing technology. (a) Cut woody stems of grape (*Vitis* spp.) with bases immersed in forcing solution and buds beginning growth. (b) Shoots elongated sufficiently to be excised for use as explants for micropropagation. (c) New recently emerged red epicormic shoots being forced on a 4 cm diameter walnut stem segment. (d) 2–5 cm long forced shoots ready to be excised for use as explants for micropropagation.

been accomplished and will continue to be pursued in the fields of organogenesis and embryogenesis, those topics will not be considered further.

Explant Disinfestation

Nearly all reports regarding culture establishment initially describe the disinfestation technique, which employs a chemical treatment to kill organisms on the surface of the explant. Bacterial cells, fungal spores, and some arachnid or small insect pests may inhabit the explant surface and when the explant is placed on the culture medium these contaminants can multiply and destroy the explant. The most common disinfestant procedure employed is soaking the explants in bleach (sodium or calcium hypochlorite solutions), a potent oxidative agent that in optimal concentrations and durations will kill the undesirable organisms. A wetting solution such as Tween 20 usually is added to the bleach solution. This will aid in good surface contact and improved kill of unwanted organisms. The bleach soak is often preceded by several soapy water rinses to remove dust and other extraneous material from the explant. Treatment with sodium dichloroisocyanurate (NaDCC) has been reported to be as effective as sodium hypochlorite for greenhouse and field-grown *Citrus* (Niedz and Bausher, 2002). Other chemical treatments have also been utilized such as ethanol, hydrogen peroxide, and mercuric chloride. The latter chemical and other poisonous compounds are dangerous to the operator and often represent a disposal problem; their use is therefore discouraged. Newer chemicals, such as zerotol (Aftab *et al.*, 2005), have exhibited promise as disinfesting agents and no doubt additional compounds will be found for future use.

Medium Disinfestation

The most common method to sterilize the medium is the use of an autoclave to provide heat treatment under pressure. A typical treatment is 121 °C for 20–30 min. Times may vary and when using a new autoclave one or more test runs is

Figure 2 (a) Green, leafy walnut shoot harvested for micropropagation explants. The leaves are removed, as in (c) and surface disinfested. Following disinfestation and rinsing in sterile water, the shoot is cut into nodal and apical explants (b). (c) Hibiscus nodal explants with new growth, toward the end of Stage I.

recommended. In recent years, especially for small-scale research or commercial operations, the use of a microwave oven is an inexpensive alternative to an autoclave (Tisserat *et al.*, 1992).

Medium Gelling

Choice of gelling agent or use of liquid medium can have an impact on the success of the micropropagation process. Debergh (1983) compared seven different brands of agar at five different concentrations for gelling Murashige and Skoog (1962) medium when micropropagating *Cynara scolymus* and *Oreopanax nymphaeifolia*. He found numerous differences in gel strength and chemical characteristics of the medium with differences in a defect referred to as hyperhydricity, and related to cytokinin and water availability. Agar gel strength was related to water availability, with a more firm gel providing less water availability and therefore less hyperhydricity. Working with more defined agar sources and agar alternatives Wetzstein *et al.* (1994) observed that gel strength was influenced by gelling agent and by choice of medium. Woody Plant Medium (WPM) and Gamborg B5 (GB) was generally more firm than MS, Gel-gro had greater gel strength than either agar tested, and autoclaving caused a decrease in pH of all media. Like Debergh, they emphasized the importance of medium choice, gelling agent, and sterilization protocols. Use of agitated liquid medium was employed by Morel (1964) and Preece (2010) has shown that large shoot masses can be micropropagated successfully in shallow stationary liquid medium (**Figure 3(c)**). It is important to use agars of high purity for plant tissue culture. Gelcarin gums are also widely used in micropropagation. They create a gelled clear medium compared with the gelled cloudy medium with agar. Gelcarin gums may result in better shoot growth *in vitro*, but hyperhydricity can be a problem. To solve this, a mixture of half strength agar with some gelcarin gum results in low hyperhydricity and good shoot growth.

Medium Composition

It is acknowledged that the culture medium must provide adequate nutrition and an energy source because unlike an intact plant, the explant generally cannot adequately produce its needs. A typical micropropagation medium contains both inorganic macro- and micronutrients; an energy source, usually sucrose, although other sugars and complex carbohydrates are sometimes employed; organic chemicals such as vitamins, amino acids, and hormone-like plant growth regulators, such as auxins, cytokinins, gibberellins, and occasionally others. In some medium formulations complex substances are included such as coconut water (liquid endosperm), tomato juice, and purees of other fruits and vegetables. A comparison of several commonly used media is presented in Hartmann *et al.* (2011). Nas and Read (2004) developed a medium based on the chemical composition of hazelnut (*Corylus* spp.) kernels, making the assumption that nourishment of explants *in vitro* could be consistent with the nutritional needs of the developing embryo *in situ* during germination. They also presented a comparison of the constituents of the Nas and Read medium with MS and other media.

(c) Hibiscus axillary shoot proliferation on stationary liquid medium. (d) Growth room for Stage II cultures.

Culture Environment

A clean room for aseptic transfer and subsequent growth of the explants (Figure 3) is essential to the success of any micropropagation enterprise. Light level (photon flux), photoperiod, and light quality are all important, particularly when green leafy explants are used. In some cases, absence of light is preferred, as in the case of *Anthurium andreanum* (Pierik *et al.*, 1979), and Miller and Murashige (1976) showed that tropical foliage species – which often are jungle understory species – benefited from culture under relatively low light. However, many researchers have reported that higher light levels promote shoot growth and more photosynthetic activity by green explants (Werckmeister, 1971; Pennazio and Radolfi, 1973; Hasegawa *et al.*, 1973). Reported optimum photon flux levels are varied, but many fall into a range of 70–80 μmol m^{-2} s^{-1} (Hutchinson, 1984; Economou, 1982; Villalobos *et al.*, 1984). Optimum light levels vary with the species, and the literature should be consulted when beginning with any new species.

When considering photoperiod, species that are physiologically responsive in nature, i.e., flowering under short days (SD, chrysanthemum) or long days (LD, carnation) and tuberization (SD, dahlia), will likely respond similarly *in vitro*. However, in most cases of such morphological responses, for example, flowering in chrysanthemum, the response is undesirable for *in vitro* culture because such responses will be competitive with the desired goal of micropropagation. Typically microcultures are incubated under 16 h photoperiods. This is especially necessary with woody species to keep them from going dormant.

Light quality, as mentioned earlier regarding stock plants, can likewise influence endogenous hormone levels and thus affect *in vitro* performance. If there is a predominance of red light, it may increase endogenous cytokinin levels and enhance

shoot proliferation (Economou and Read, 1986b). Research on light quality is continuing and may have additional impact on practical micropropagation in the future. Most commercial and research laboratories use cool white fluorescent lamps, or fluorescent lamps designed for growing plants.

Temperature in Micropropagation

As is true for intact plants, temperature governs numerous processes and plant growth in general. Within limits, growth and development increase with rising temperature. Culture temperatures in the range of 20–27 °C are commonly used. When considering appropriate culture temperatures, the natural habitat of the species to be cultured should be considered, for example, 32–39 °C for species of tropical origin.

Culture Atmosphere

The atmospheric constituents in the culture room and in the culture vessel could logically have a profound impact on explant responses *in vitro*. Generally, little research has been done on the culture room atmosphere, but humidity, carbon dioxide, oxygen, and ethylene levels have been investigated. Typically the gaseous atmosphere inside the culture vessel is 90% relative humidity or higher. This high humidity presents a problem for acclimatization, which is addressed under Stage IV in this article. Maximum relative humidities are highest for liquid cultures and those that employ low levels of gelling agents; high concentrations of agar, for example, approximately 1.0%, create a stiffer medium and lower relative humidity (Debergh *et al.*, 1981; **Figure 5**).

Carbon dioxide levels in the culture atmosphere can influence photosynthesis for green leafy explants. Reuther (1987) demonstrated advantages for CO_2 enrichment of grape, *Spathiphyllum*, and African violet micropropagation. Researchers have pursued autotrophic culture to enhance micropropagation efficiency (see Stage IV, Kozai (1991)) and the addition of CO_2 to combat the detrimental influence of ethylene buildup in the culture (Van der Plas and Wagner, 1986).

Ethylene inhibition of explant growth and organogenesis is an important consideration, because it is clear that cultures that contain auxin in the medium and contain living tissue (explants) can produce ethylene. When ethylene builds up in sealed vessels, it can inhibit and even kill the plant material being cultured. Gavinlertvatana *et al.* (1979) reported growth suppression of petunia and dahlia and Mingo-Castel *et al.* (1976) showed that ethylene inhibited tuber formation in etiolated potato sprouts, but elevated CO_2 levels stimulated tuberization. The negative effects of ethylene have been counteracted by the treatment of explants with silver nitrate or cobalt chloride, but scrubbing ethylene from the vessel atmosphere with potassium permanganate had little effect on ethylene-induced growth suppression. Economou (1991) has reviewed the positive and negative effects of ethylene on *in vitro* cultures.

Because oxygen is required for respiration of all living cells, it would seem obvious that oxygen levels could be important for micropropagation. Agitation of liquid cultures aerates the medium when propagating orchid meristems, for example. Stationary liquid medium can be used if it is sufficiently shallow to allow the shoot cultures adequate oxygen (Preece, 2010). Gelling agents support the plant material allowing good aeration.

When working with gelled cultures, oxygen in the head space atmosphere is also important, although oxygen enrichment of the culture atmosphere has not been investigated to a large extent and both stimulation and inhibition have been reported for culture atmosphere enrichment.

Meristem Culture

The apical meristem area is often free from pathogens, including viruses, because vascular differentiation occurs in daughter cells that differentiate from meristematic cell divisions, not in the cells in and immediately around the apical meristem (Preece, 2003). Because it is difficult to excise only the meristem, young leaf primordia are also included, making the explants micro shoot tips, typically 0.4–0.5 mm in diameter. Micro shoot tips are widely used to escape viruses in perennial, clonally propagated crops. Frequently stock plants or cultures also receive thermotherapy as a further measure to produce plants free from important pathogens.

Morel (1960) used this technique to produce virus-free orchids. In practice, the process involves starting with an elite plant that usually receives heat treatment, from which the meristem tip is excised and used as the explant. Following culture, possibly several re-cultures of the micro shoot tip, resulting shoots and plants are tested for freedom from those pathogens that can be detected. This latter step may involve indexing for viruses, bacteria, or other diseases. It is standard practice to obtain specific pathogen-tested stock plants for a wide variety of asexually propagated crops, including potato, banana, pome fruits, several citrus species, chrysanthemum, and many others (Klopmeyer, 2000). An interesting example is the use of meristem cultures for the elimination of Pierce's disease in Muscadine grape, *Vitis rotundifolia* (Robacker and Chang, 1992). For a review of the process of escaping pathogens using this technique, see Sangwan *et al.* (1987) and Milošević *et al.* (2012).

Stage II: Multiplication

The multiplication stage capitalizes on the stimulation of axillary buds from the explant, which in turn can produce many more shoots that have axillary buds that with repeated subculturing can result in an exponential increase of explant numbers. Subsequently these shoots can be cut into numerous pieces, each with at least one axillary bud, for further subculturing. The resulting shoots can then be induced to produce adventitious roots and grown on as intact plants (see Stages III and IV, **Figures 2–4**).

As noted earlier, cytokinins, or a ratio of cytokinin to auxin in which cytokinin dominates, can lead to bud production, shoot proliferation, and potential new plantlets. When using an agar-gelled medium, the shoots may not elongate well or produce adventitious roots in a satisfactory manner. Maene and Debergh (1985) demonstrated that liquid additions to existing 'exhausted' cultures could help to alleviate this

Figure 4 (a) Walnut microshoots that have been cultured in darkness to etiolate the shoots to enhance adventitious root initiation. (b) and (c) *In vitro* rooted microshoots of trifoliate orange ready to transplant to flats ultimately to be used as clonal rootstocks for citrus. (d) *In vitro* rooted microshoot of cherry, ready for transplanting into greenhouse growing medium.

problem. By adding liquid MS medium that contained kinetin instead of the BA that had been used in the multiplication medium, they were able to stimulate shoot elongation of *Philodendron* and *Cordyline*. Inclusion of charcoal in the liquid medium added to *Philodendron* cultures, along with kinetin, gave uniform elongation of the microshoots. They theorized that the charcoal overcame the after-effect of high BA in the Stage II cultures. Stationary liquid medium can also be used to enhance shoot elongation, and is useful on species that are not prone to hyperhydricity (Preece, 2010).

A large number of plant species and gentypes have been successfully micropropagated in the decades since Murashige's (1974) listing of over 100 species and more than 50 genera that had been micropropagated to that date. Examples of herbaceous and woody plants are now routinely micropropagated, among many, including the following:

- Herbaceous/ornamentals:
  - *Aechmea* – Cueva *et al.* (2006)
  - *Gardenia* – Hatzilazarou *et al.* (2006)
  - *Philodendron* – Jámbor-Benczár and Márta-Riffer (1990)
  - *Pulmonaria* – Stimart *et al.* (1998)
  - *Tillandsia* – Cueva *et al.* (2006)
- Woody ornamentals:
  - *Acanthopanax* – Yang and Read (1997)
  - *Acer* – Preece *et al.* (1991a,b)
  - *Berberis* – Uno and Preece (1987)
  - *Cercis* (red bud) – **Figure 8**
  - *Hibiscus* – Airò *et al.* (2009, **Figures 2** and **3**)

- Fruits:
  - *Citrus* – **Figure 4**
  - *Malus* (apple) – Zimmerman (1984)
  - *Olea* – Leva (2011)
  - *Passiflora* – Faria and Segura (1997)
  - *Prunus* –**Figures 4** and **6**
  - *Rubus* – **Figure 7**
  - *Vaccinium* – Grout and Read (1986)
  - *Vitis* – Gago *et al.* (2009, **Figure 1**)
- Nut crops:
  - *Castanea* – Yang *et al.* (1986)
  - *Corylus* – Nas and Read (2001)
  - *Juglans* – Leslie *et al.* (2010, **Figures 1–4**)
  - *Pistachia* – Benmahioul *et al.* (2012)
- Medicinals and herbs
  - *Allium* – Mohamed-Yasseen *et al.* (1993)
  - *Balanites* – Gour *et al.* (2007)
  - *Hypericum* – Karppinen *et al.* (2006)
  - *Rosemarinus* – Tawfik *et al.* (1992)
  - *Satureja* – Arrebola *et al.* (1997)

At times, the available plant material may be limiting, leading researchers to be concerned about reliability of their investigations and commercial propagators to question new protocols. One approach to addressing this problem has been the studies of Nas *et al.*, (2005) in which experimental designs were tested when there was a limited amount of potential explant material. They employed two designs that they proved to be effective when explant material is limited, Plackett–Burman Design (PBD) and fractional factorial design (FFD). Although limiting information on treatment interactions when PBD or FFD are used, their results indicated that several factors could be tested when explant material is limited and would facilitate prioritizing the most important factors. Subsequently these results can provide guidance when sufficient numbers of explants become available for larger experiments.

Stage III: Pretransplant Stage

Steps in the Adventitious Rooting Process

The goal with Stage III is both root initiation and development to complete the formation of new clonal plants that will grow in the greenhouse or field. Rooting can be accomplished *in vitro* in the tissue culture incubation room or *ex vitro* in a greenhouse or growth chamber. When rooting is *ex vitro*, Stages III and IV, rooting, and acclimatization are combined, which gains efficiency if both rooting and acclimatization percentages are high. With some species, especially herbaceous plants, including many foliage plants, rooting occurs during Stage II, the shoot proliferation stage, thus allowing Stage III to be skipped. However, rooting during Stage III is critical for many species, especially woody plants, including ornamentals and fruit and nut crops.

The process of adventitious root formation from stem cuttings and microcuttings follows a predictable path with changing requirements as the new root system forms. Rooting is essentially a wound healing process. Plants have the remarkable ability to regenerate missing parts after wounding. Propagators have for centuries been utilizing the plant wound healing responses to propagate billions of superior plants by generating roots on stem cuttings and stems on root and leaf cuttings. The result is the production of uniform clonal crops of the best selected individuals.

Root formation. Both microshoots and stem cuttings are composed entirely of cells and tissues that formed and grew as parts of shoot systems and consist of cells that constitute the buds, stems, and leaves. For rooting to be successful, a small portion of the cells in the stems near the vascular tissue must convert into root meristematic cells that will divide and subsequently form a functioning root with a vascular connection to the shoot. This must happen at multiple locations around the stem for optimum root distribution and anchorage.

Rooting has long been recognized as a multistep process of induction, initiation, and expression (Kevers *et al.*, 1997, 2009). Rooting microshoots and normal 'macro' stem cuttings follows the same sequence of events. Cells that formed as part of a stem must change to perceive a signal, such as auxin and polyamines, which induces them to become root meristematic cells that will begin a coordinated series of cell divisions to form a root initial. That initial must then elongate to express a functioning root, providing anchorage, support, and both water and mineral nutrient uptake.

Not all cells in a stem have the competence to perceive a signal that will induce them to begin dividing to form root meristems (growing points). Christianson and Warnick (1985) divided the process of adventitious shoot or root production into acquisition of cellular competence, those cells being induced, and then the differentiation and growth of the organ. Viewing these three phases as separate events, with each one subsequently depending on the previous phase makes various procedures used for rooting microshoots more understandable.

Rooting varies among genotypes, including among cultivars of the same species. This is an indication that the ability to acquire cellular competence is blocked or inhibited in some genotypes (Christianson and Warnick, 1985). The ability to acquire cellular competency changes during the ontogeny of many perennial species with cuttings from juvenile forms generally rooting in higher percentages with more roots than cuttings from adult forms of the same plants (Hartmann *et al.*, 2011; Preece, 2003, 2008). Cellular competency is induced by etiolation of whole shoots (**Figure 4(a)**), or by excluding light from the bottom of cuttings (Murray *et al.*, 1994). Additionally, cellular age and position in relation to other cells affects acquisition of competency (Wilson, 1994).

Auxin has been considered an important signal for adventitious root initiation since the 1930s (Cooper, 1935; Hitchcock, 1935; Zimmerman and Wilcoxon, 1935). Auxin occurs naturally as IAA and phenylacetic acid (PAA), with IAA often having greater activity. Exogenously applied auxins are primarily IBA and NAA. These can be incorporated into the nutrient medium for *in vitro* rooting, or applied to the bases of microshoots or macrocuttings before planting in a rooting medium.

Polyamines, especially putrescine, are also important for root initiation. For example, during the induction period of adventitious root formation of mung bean (*Vigna radiata*) from 0 to 24 h, both IAA and putrescine levels increased (Nag *et al.*, 2001). When rooting *Nothofagus nervosa* microshoots,

Martinez Pastur *et al.* (2007) found that polyamine content in the tissue was highest before root emergence and therefore added 10 μM spermine to their culture medium when rooting.

Auxin is used predominantly for rooting microshoots and macrocuttings. Polyamines likely play an important endogenous role, but are seldom used when rooting cuttings or microshoots. Microshoots themselves contain and produce natural auxins, such as IAA, which also contribute to rooting. The addition of exogenous auxin makes rooting possible in some genotypes and greatly increases rooting percentages and root numbers per microshoot in many others.

Induction is when cells that have acquired competence, cells are induced by the rhizogenic action of auxin and other plant growth regulators, such as polyamines. Induction occurs in a short time of hours or days depending on genotype (Christianson and Warnick, 1985). Once induced, microcuttings can be transferred to medium with no auxin and root development will proceed. Within 24 h of exposure to 3 μM IBA, there was an increase in starch accumulation in vascular bundles and surrounding cells of 1 mm stem slices of apple microshoots (Jasik and De Klerk, 1997), which is likely an early step in dedifferentiation into a root meristem.

Caution must be exercised when using auxins for rooting. Although they appear essential for root initiation at relatively low concentrations, at relatively high concentrations they inhibit root elongation. A typical sign of auxin overdose is short, larger diameter than normal, very slow growing roots. Higher amounts of auxin act as herbicides and damage or kill plants. Therefore, it is important that a concentration of IBA or NAA is applied as a short exposure or that the concentration will be sufficient to stimulate root initiation without being inhibitory to elongation.

Although not visible to the propagator, new root meristems can form quickly. New cell divisions were visible 48 h after apple microshoot stem slices were exposed to IBA and were forming meristems after 72 h (Jasik and De Klerk, 1997). The initials of root primordia were detected 96 h after IBA treatment. That is why the auxin treatment can be removed after a short exposure with no subsequent effect or the removal may even result in improved rooting.

The remainder of the adventitious rooting process is normal root growth activity. The new root apical meristematic cells divide and daughter cells differentiate and form the tissues of functioning roots. During this process, each new root establishes a vascular connection with the shoot to supply it with water and mineral nutrients in return for photosynthate.

Methods for Rooting Microshoots

If microshoots do not form roots during the multiplication stage, they must receive special treatments to initiate and grow an adventitious root system. Microshoots may be rooted *in vitro* and then acclimatized to the ambient environment, or they may be rooted *ex vitro*, thus combining rooting and acclimatization.

Ease and success rate of rooting determine which method is used on a particular cultivar. The more cost-effective method is to root microshoots *ex vitro*. *Ex vitro* rooting saves an additional *in vitro* transfer to rooting medium and speeds acclimatization making micropropagation more efficient. *In vitro* rooting is used if *ex vitro* rooting and acclimatization facilities are lacking, if success rates are low with *ex vitro* rooting, and at the discretion of the laboratory manager.

In vitro rooting. The ingredients in the medium and the incubation conditions are easy to change when *in vitro* conditions are used to promote root initiation and early development. Nutrient salt formulations may remain the same, be changed, or reduced, often to half strength macrosalts, and relative humidity reduced by the use of ventilated lids (**Figure 5**). The light and temperature culture incubation conditions can be changed for rooting. Many microshoots are incubated in darkness for a period for root initiation and then transferred to lighted conditions.

The rooting nutrient medium on which freshly cut microshoots are placed generally contains auxin. Typically micromolar concentrations of IBA and/or NAA are added to the medium before autoclaving. The concentration of auxin depends on the species and cultivar. This information is typically available online using a scholarly search engine, such as Google Scholar http://scholar.google.com/. Typically the name of the plant, the words '*vitro*' and 'root' (or adventitious root) in the search string will yield specific information. If the literature is lacking for a particular plant, use close relatives in the search to determine how they responded.

Because it is recognized that the same concentrations of auxin that stimulate adventitious root initiation can inhibit root development, some use a two media approach. When microshoots of *Cotinus coggygria* were on medium containing 10 μM IBA for 5 days before transfer to auxin-free medium, 100% rooted; whereas only 40% rooted with continuous culture on medium with the 10 μM IBA (Metivier *et al.*, 2007). Padilla and Burgos (2010) cultured olive microshoots on media containing up to 4 μM IBA for 2 weeks followed by transfer to basal medium without auxin that resulted in 65–93% rooting, depending on cultivar.

In some cases, IBA solutions have been applied to microshoots as a basal dip for one minute or more. Tsvetkov *et al.* (2007) obtained their best rooting of *Sorbus domestica*

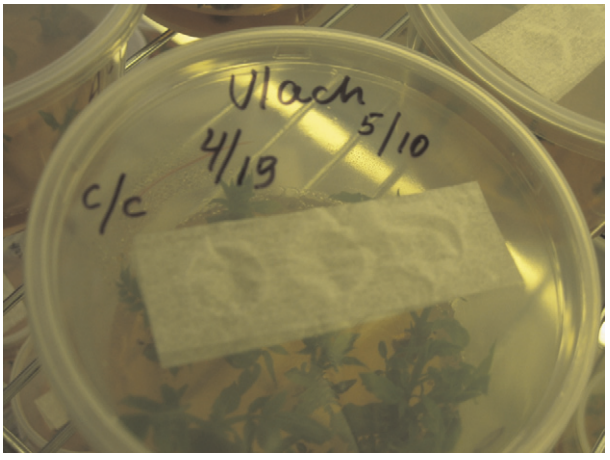

Figure 5 Surgical micropore tape provides ventilation to this vessel of shoots being rooted; this helps reduce relative humidity and prepares the new plants for the greenhouse environment.

microshoots when they were dipped in a 14.8 μM IBA solution for 80 s before being placed on basal medium.

Darkness during or before rooting can increase rooting success and synchronicity of rooting among microshoots. Etiolation, development of shoots without light, will increase cellular competency for adventitious rooting (Murray *et al.*, 1994). When walnut microshoots were etiolated, rooting was better with faster emergence of roots than from green shoots (Leslie *et al.*, 2010); however, the etiolated shoots were brittle and required more careful handling.

Culturing green microshoots on rooting medium in darkness for a relatively short period can greatly enhance rooting. A period of darkness for 4–7 days on a half strength Murashige and Skoog medium containing 1 μM phloroglucinol and 1.4 μM IBA followed by incubation under lighted conditions resulted in better rooting of 'Delicious' apple microshoots than if cultured only in light or in darkness for longer periods (Zimmerman, 1984). When culturing 'MM106' apple rootstock microshoots on medium with 4 μM IBA in darkness for 0–10 days, it was discovered through histological investigation that root induction occurred during the first 3 days or less in darkness and that conical root primordia were visible by day 7 (Naija *et al.*, 2008). Timing of treatment in darkness is critical and may need to be determined for each crop or genotype; nevertheless, it can greatly enhance rooting success.

Some species root best if the tops of the microshoots are lighted and the basal portion in the medium is in darkness, similar to the way that macrocuttings are rooted in a greenhouse medium under mist. Darkening of the medium can be achieved by painting the outside of culture vessels black to slightly above the level of the medium and covering the medium with sterile polycarbonate granules or other light excluding substance or darkening the medium itself by adding activated charcoal. At times a greenhouse medium, such as vermiculite, which also excludes light is used for *in vitro* rooting after being wetted with the nutrient medium.

It was shown that darkening the bases only of microshoots increased rooting of almond, peach, and olive (Rugini, 1988) and apple (Mencuccini and Rugini, 1993) compared with controls incubated either in darkness or under lights. However, in a separate study, Mencuccini and Rugini (1993) reported that basal darkening had little effect on rooting almond, apricot, chestnut, jojoba, and olive microshoots and was inhibitory to walnut. Therefore, if rooting success is below what is desirable, basal darkening may be helpful.

Ex vitro rooting. If rooting percentages are similar, *ex vitro* rooting can be more efficient and cost effective than *in vitro* rooting (Leva, 2011). Costs are higher when rooting *in vitro* because of the ingredients, preparation time, autoclaving media, labor for transfers and moving cultures, and incubation space. Movement to the greenhouse is similar between *in vitro* and *ex vitro* rooting, and transplanting time may be similar or slower when there are roots on the microshoots (**Figures 4** and **6**). Efficiency is gained by rooting *ex vitro*. It has been reported that the root quality of walnut microplants is superior when the roots form *ex vitro* under fog than *in vitro* in a gelled medium (Leslie *et al.*, 2010).

Ex vitro rooting can be an improvement on *in vitro* rooting. Although *in vitro* microshoots of *Gardenia jasminoides* rooted in 10 days, compared with 14 for *ex vitro* microshoots, all microshoots rooted *ex vitro* survived acclimatization compared with 80% survival for *in vitro*-rooted microshoots (Hatzilazarou *et al.*, 2006). Poorer survival of microshoots rooted *in vitro* compared with *ex vitro*-rooted microshoots was also reported for walnut (Leslie *et al.*, 2010).

It may be necessary to treat microshoots with auxin before planting in rooting medium for *ex vitro* rooting. Pistachio microshoots treated with 2% IBA in talc rooted *ex vitro* at 79% compared with 48% rooting for the controls (Benmahioul *et al.*, 2012).

Improved *ex vitro* rooting can also be obtained with auxin applied as a liquid dip applied to the basal portion of microshoots. A 15 min pulse in 250 μM IBA caused 90% of the tree species *Melia azedarach* microshoots to root compared with no rooting on control microshoots (Husain and Anis, 2009). A 2 h dip in an aqueous solution of 588 μM IBA caused 90% of *Malus zumi* microshoots to root compared with 20% rooting of controls (Xu *et al.*, 2008).

Perhaps because of a reversion to juvenility, increasing time being multiplied *in vitro* can increase rooting of microshoots. Leva and Petruccelli (2012) tested rooting up through seven subcultures and found that rooting was best after the seventh subculture.

Facilities, the species, shipment method, customer demand, and managerial preferences all dictate how microshoots are rooted. Species that root very easily or root during the shoot proliferation phase can be acclimatized to the *ex vitro* environment quickly. It is the challenging species that receive special attention, regarding lighting, auxin treatment, rooting *in vitro* or *ex vitro*, and other factors. The clones that are difficult to root demand greater prices from customers because rooting is an impediment to efficient production. Rooting can be improved if it is approached as a multistep process of acquiring competency, root initiation, and subsequent root growth. All of these steps must be considered and addressed, especially with the more difficult-to-root clones.

Stage IV: Acclimatization

Acclimatization of microplants to the *ex vitro* environment of the greenhouse and field can be a time of the greatest losses of plants in the micropropagation process (Preece, 2001, 2010; Preece and Sutter, 1991). Shoots, and leaves in particular that form *in vitro* on many species are uniquely unsuited to the ambient environment, consequently there must be a gradual hardening process during which microplants produce new leaves in the acclimatization and post-acclimatization environments. See the leaves on the plantlets in **Figure 7**, the majority were formed during and after acclimatization compared with the leaves in **Figures 4** and **6** that formed *in vitro*.

Humidity Control

A primary challenge with establishing microplants in the ambient environment is the change in relative humidity. The *in vitro* environment is typically 100% relative humidity

Figure 6 (a) and (b) *In vitro* rooted micropropagated cherry plantlets ready for transplanting into a sphagnum peat greenhouse medium before placement under high relative humidity for acclimatization. (c) The cherry plantlets being planted as the first step in greenhouse acclimatization. (d) Walnut plantlets being planted in a flat before being placed under high relative humidity in a greenhouse.

(see the condensation inside of the culture vessels in Figure 4b). The leaves that form on these *in vitro* microshoots do not develop the same mechanisms to prevent water loss as plants growing at lower humidity levels. In the saturated *in vitro* atmosphere the development of the waxy cuticles on leaves is greatly reduced compared with the same clone grown *ex vitro* (Hazarika, 2006; Preece, 2001, 2010; Preece and Sutter, 1991). Additionally, the stomatal apparatus often does not function and the stomata remain continuously open, even at night or during dessication.

Perhaps because of a combination of low light and the high humidity, there are much greater air spaces and less tight packing among the cells of the *in vitro*-produced leaves than those grown in the ambient environment (Brainerd and Fuchigami, 1981; Preece and West, 2006; Preece, 2010). Leaves produced *ex vitro* are approximately three times thicker in cross section and the palisade cells containing chloroplasts are tightly packed and often stacked in multiple layers, whereas *in vitro*-produced leaves have only one layer of palisade cells with intercellular spaces. During acclimatization, the first new leaves that form are thin and similar to *in vitro* leaves; however, as new leaves develop, they gradually become more like normal leaves that grow on plants in the greenhouse or field. Initially the new leaves that form during acclimatization have tightly packed palisade cells, indicating a transition to higher light and lower relative humidity.

In vitro rooting is often in vessels with ventilated lids (Figure 5), which can lower humidity and begin the transition of microplants to the *ex vitro* environment. For example, ventilation caused lower water content, which thus increased epicuticular waxes on the leaf surfaces, and resulted in a higher resistance to water loss on jojoba propagules (Mills *et al.*, 2001), which all contribute to acclimatization success.

If ventilated lids still maintain a high relative humidity, loosening, tilting open, and removing lids of culture vessels following *in vitro* rooting but before transplanting will help prepare microplants for the ambient environment. With desert date (*Balanites aegyptiaca*) it was necessary to gradually unscrew lids of culture vessels before transplanting into vermiculite to

Figure 7 Rooting and root development on clonal microplants immediately following acclimatization. (a) and (b) Walnut plantlet being acclimatized and showing root development through a peat pot containing a sphagnum peat-based container (a) or in a similar medium removed from a plastic container. (c) Blackberry plantlet showing root development along the outside of the sleeve containing a similar peat-based medium. (d) and (e) Root development on clonal walnut rootstock micropropagated plants after acclimatization and removal of the growing medium.

achieve a 43% survival of this recalcitrant species (Gour *et al.*, 2007).

In vitro-rooted microplants should have a good, healthy root system at the time of transplanting, as with any transplant (Figures 4 and 6). To provide good anchorage, new adventitious roots should emerge from all sides of each new microplant. Before transplanting, new microplants must not be allowed to overheat, become too cold, or desiccate. Microplants are typically transplanted into small pots, starter blocks, or flats containing suitable growing medium and then moved to the acclimatization environment where new roots will begin to grow and shoots will elongate in a short time, or after a lag period of little or no growth, depending on the species and cultivar (Figure 7).

Because of the poor adaptability of *in vitro* leaves to the *ex vitro* environment, it is essential that the microplants be placed in a high relative humidity environment, such as under fog or intermittent mist located in a greenhouse or humidity tent (Figure 8). The goal is to minimize transpiration and not to soak the plants. Multiple types of enclosures are available to

Figure 8 Acclimatization areas. (a) Clonal walnut rootstock plants being acclimatized within a clear plastic tent. (b) 'Forest Pansy' Red Bud (foreground) and blackberry plants during acclimatization under a white plastic humidity tent with evenly spaced overhead mist nozzles. (c) and (d) Walnut microplants being acclimatized in a greenhouse with a fog system filling the greenhouse with humidity in (d).

provide a highly humid environment, and can be as simple as a plastic bag over a potted microplant, to benches covered with clear or white plastic, plastic tunnels, hard plastic and vinyl, or glass domes or other enclosures (Preece, 2010). Plastic and other tunnels may contain fog or intermittent mist systems.

The relative humidity should be gradually reduced as the plants adapt to the acclimatization environment. An example is a gradual reduction in relative humidity from the initial 100–60% over a 3-week period, which worked well for *Vitis vinifera* 'Albariño' (Gago, 2009). This gradual reduction in humidity can be achieved by venting humidity tents and other enclosures, adjusting the mist or fog system controls to decrease the 'on' times and increase the 'off' times.

Shading

In addition to high relative humidity, microplants are often acclimatized under shade. *In vitro* leaves are shade leaves because they develop under approximately 35–80 μmol m^{-2} s^{-1} and are therefore poorly adapted to sunlight. In separate studies, when different levels of shade or light were tested, survival of *Heliconia bihai* (lobster claw) was highest (>90%) under the highest levels of 70% or 80% shade (Rodrigues *et al.*, 2005). *Musa* (banana) microplants acclimatized best under the highest levels of 50% or 70% shade (Scaranari *et al.*, 2009) and *Doritaenopsis* orchids had best growth and survival when acclimatized under the lowest light levels of 50–150 μmol m^{-2} s^{-1} (Hahn *et al.*, 2009).

Shade can be provided by using a semiopaque plastic for a humidity tent, rather than clear polyethylene. Various shading materials are used, including shade cloth or fabric that is available from approximately 20–90% shade in various increments. Wood or aluminum lath is also an effective way to apply shade to plants. For acclimatization, the fabric should provide at least 50% shade and typically should be combined with intermittent mist or fog.

Substrates

There are many different greenhouse media used during acclimatization, ranging from plugs and starter blocks (**Figure 7**) to sphagnum peat- or tree bark-based media in flats or pots (**Figure 6**, Preece, 2010). The specific acclimatization environment dictates which substrate will be cost effective and contributes to the production of high-quality plants. For example, a medium that holds too much or too little water for

the situation will result in reduced acclimatization success. A well-drained medium, such as perlite, vermiculite, or sand might be appropriate in a wet environment, such as under mist, or either peat or bark mixed with the perlite or vermiculite might be suitable for fog or other high humidity conditions.

An ideal medium will provide good water-holding capacity for the situation; have adequate pore spaces to provide a balance of air (especially oxygen) and water-holding capacity; be easily wettable; provide good anchorage; be of a proper pH for the crop; if used to grow the plants, be able to hold nutrients (high cation exchange capacity); be inexpensive and readily available; and be free from pathogens, insects and pests, and toxic substances. Some media are hydrophobic when dry, such as sphagnum peat and some tree barks. These can be used if a detergent-type wetting agent is added to break the surface tension of the water. Otherwise, water will run off and not soak the medium creating droughty conditions for the microplants, often leading to stunting or death.

Beneficial soil microflora can be considered during acclimatization and may contribute to acclimatization success. In particular, inoculations with mycorrhizal fungi have been shown to be very helpful. *Vitis vinifera* 'Pusa Navrang' microplants grown in medium inoculated with single or mixed strains of arbuscular-mycorrhizal fungi had an 81–91% survival rate compared with only 45% for noninoculated plants (Krishna *et al.*, 2004).

Mycorrhizal inoculation can also enhance subsequent growth and quality of the fully acclimatized plants, resulting in a higher quality product. For example, the following species had both greater survival and growth compared with control plants when inoculated with the arbuscular-mycorrhizal fungus *Glomus viscosum*: *Cynara cardunculus* (Cardoon), *Cucumis melo* var. *inodorus* (melon), *Origanum vulgare* subsp. *hirtum* (Greek oregano), and *Spartium junceum* (Spanish broom, Ruta *et al.*, 2009).

Some growers add the beneficial fungi *Trichoderma* spp. to their peat-based medium for acclimatizing microplants and their subsequent growth (Hoare, 2001). *Trichoderma* spp. are avirulent plant symbionts that colonize plant root surfaces protecting the roots from several pathogens, as well as often enhancing root growth, nutrient uptake, abiotic stress tolerance, and overall productivity (Harman *et al.*, 2004). Addition of *Trichoderma* can be beneficial whenever growing plants.

Encapsulated Vegetative Explants

Sodium alginate, gelled with calcium chloride ($CaCl_2$) can be used to encapsulate nodal explants for storage, or to use in a manner similar to an artificial seed that can be planted for growth and acclimatization. The alginate matrix protects the nodal segment and emerging plant from desiccation and provides the nutrients of the tissue culture medium within the matrix. Results have varied with species and acclimatization conditions.

Microbial infection can be a problem when planting encapsulated nodal segments because of the ingredients in the alginate matrix (nutrient medium salts, organics, sugar, and others). Researchers have addressed this problem. Bapat and Rao (1990) previously had experience with microbial infection when planting alginate beads containing 0.5 cm long nodal segments of mulberry (*Morus indica*). These were planted in autoclaved soil in Petri dishes. When the encapsulation matrix contained 50 mg l^{-1} Carbendenzim, 63% formed plants, whereas when the matrix contained 50 mg l^{-1} Bavastin, only 21% formed plants. Refouvelet *et al.* (1998) used the carbamate eserine, *p*-hydroxymercuribenzoate (*p*-HMB), which was applied as a spray every 4 days, to encapsulated lilac (*Syringa vulgaris*) buds before preacclimatization in an enclosed chamber on Sorbarods® in a nonsterile environment for 45 days. Survival was up to 81% in the greenhouse.

Problems with decay, necessitating the use of pesticides may be related to planting condition. Preece and West (2006) used no fungicides and found that the only encapsulated nodal segments of hardy hibiscus (*Hibiscus moscheutos*) that survived were planted in vermiculite under intermittent mist. None survived if under fog or hand watering, or if planted in perlite or a peatlite medium (two sphagnum peat: one vermiculite: one perlite (by volume)). Because survival was only 20% and because Sarkar and Naik (1998) gave a lighted pretreatment to encapsulated potato nodal segments with no pesticide, West and Preece also tested an *in vitro* lighted pretreatment. When encapsulated nodal segments were placed under light in the laboratory for 2–3 weeks, 100% acclimatization success was achieved under intermittent mist uncovered, in 1 cm deep furrows in vermiculite. Kumar *et al.* (2010) also achieved high acclimatization success without pesticide, but had to transfer encapsulated jojoba (*Simmondsia chinensis*) shoot tips to *in vitro* medium containing IBA for 4 weeks to produce rooted shoots for acclimatization.

Therefore, with the correct pretreatment to induce both root and shoot growth, alginate-encapsulated nodal segments can be planted like small plugs, which can be very efficient. This must be tested by genotype, and efficiencies in the encapsulation process are necessary to be cost effective.

Acclimatization under Commercial Conditions

Nurseries typically receive Stage II, freshly cut microshoots; Stage III, *in vitro*-rooted nonacclimatized microplants; or Stage IV, fully acclimatized plantlets from commercial micropropagation laboratories. Freshly cut microshoots must be rooted and acclimatized and are priced lower to the nursery than rooted or acclimatized microplants. Fully acclimatized plantlets are sold to growers for direct field planting and nurseries for growing to profitable size.

Carlton Plants, Oregon, USA (Anderson, 2001); Skagit Gardens Inc., Washington, USA (Hoare, 2001); and Meadow Lake Nursery Co., Oregon, USA (Armstrong, 2001) purchase microcuttings. Carlton Plants places microcuttings into a one sphagnum peat: one pumice medium with fertilizer, Skagit Gardens uses a seven sphagnum peat: three perlite medium with both fertilizer and *Trichoderma* and then intermittent mist with bottom heat for 4–7 days (Hoare, 2001). Meadow Lake Nursery may refrigerate the microcuttings until they can be planted. Applications of hydrogen dioxide (Zerotol®) can eliminate algae and foliar diseases.

Manor View Farm, Inc., Maryland, USA (Jones, 2001); Carlton Plants, and Skagit Gardens receive nonacclimatized rooted Stage III microplants. Manor View Farm transplants them into 72- or 98-cell plug trays and then places them into a tent with a mist system. Skagit Gardens and Meadow Lake Nursery handle them the same way as the Stage II microcuttings.

Some nurseries specialize in acclimatization and sell or grow-on microplants. With all or a portion of a nursery having focus on acclimatization, the grower gains great expertise with this system. Early recognition and control of pathogens, such as *Botrytis* (gray mold) is crucial to successful acclimatization. *Botrytis* can appear as a gray fuzzy mold and thrives in humid, stagnant environments such as those found within acclimatization tents and other enclosures.

Conclusion

Clonal micropropagation is an important component of the propagation, nursery, and orchard industries. This technology has allowed the Oregon hazelnut industry to abandon grafting and transplant micropropagated trees growing on their own roots. The California walnut industry has, for the first time, clonal rootstocks available only because of micropropagation. Walnut cuttings root poorly and not at commercially viable rates.

The micropropagation industry is having an economic impact on companies that sell the supplies and equipment, the trucking and transportation industry, the nursery industry, the forestry industry, the landscape industry, and others. Commercial companies would not devote their resources to purchase micropropagated plants unless there were sufficient demand for the product. Clearly, there is a place for micropropagation and although micropropagation will never replace grafting, layering, and rooting cuttings, it is an important component of the commercial propagation industry.

Whether grown commercially, for research, or personal pleasure, all clonal micropropagation follows the same basic pathway through the stages of micropropagation. Because axillary shoot proliferation is important, initial explants must include nodes. Axillary buds are induced to grow from the nodes, and when desired, excised, rooted, and acclimatized.

Care must be exercised to avoid adventitious shoots and only axillary shoots should be produced to ensure clonal fidelity. Adventitious shoots can show a tendency to exhibit somaclonal variation and the resulting plants may not be true-to-type. Commercial laboratories have failed because of selling plants derived via adventitious shoot organogenesis. The lack of uniformity among the plants disappointed customers, who did not make additional purchases.

Clones that establish, proliferate shoots, root, and acclimatize successfully are the easiest for meeting customer demand and the most cost effective to produce. Genotypes that offer more production challenges and either grow and multiply, root, and/or acclimatize slower and less successfully are more expensive to produce and for customers to purchase than easier genotypes. Typing 'micropropagation laboratories' into an Internet search engine will access sites with additional information about micropropagation.

Glossary

Agricultural System Model A mathematical model of soil–water–plant–climate management system.
Cover crops Short-duration crops that are planted after harvest of main crop (e.g., corn) and planting of the next main crop in rotation (e.g., soybean).
Crop simulation Computation of plant growth processes with a mathematical model.
Crop water production function Crop biomass or grain yield at different levels of water use; transpiration, evaporation and transpiration, or water supplied in the soil.
Emission scenarios Level of greenhouse gas (GHG) concentrations in the atmosphere depending upon the different scenarios of emission from various sources. In the 2000 report, the Intergovernmental Panel on Climate Change defined four possible emission scenarios in the order of increasing GHG concentrations as A1, A2, B1, B2.
Filed capacity Water retained in the rootzone after complete wetting, followed by gravity drainage for 48 hours, expressed as volume of water per volume of soil.
Plant available water (PAW) Part of the water in the rootzone that the plant can uptake, which is the difference in soil water contents between field capacity and wilting point.
Water use efficiency Crop biomass or grain yield per unit of crop transpiration or PAW.
Wilting point Water content in the rootzone at which the plants start to wilt.

Why Models in Agriculture?

The use of system models in agricultural research has accelerated in the past two decades due to increasing knowledge of the soil–plant–atmosphere system, our ability to collect massive real-time field data, unlimited computing power, and the need to address more difficult and complex issues facing us in the twenty-first century. The continued increase in world population requires continued increases in agricultural production. However, the increase in the use of fertilizers, pesticides, and water to increase production with the new higher yielding crop varieties is causing environmental problems and soil degradation. The ground and surface water quality is seriously affected by excessive leaching and runoff of agricultural chemicals at many places. The increase in soil salinity, decline in soil organic matter, and increase in soil erosion remain major problems in intensively farmed areas. The environmental concerns of the general public are challenging producers to modify farm management to protect water, air, and soil quality, while staying economically profitable. At the same time, global warming and the increased frequency of droughts and floods, water shortages due to increased urban use, and market-based global competition in agricultural production are threatening economic viability of the traditional agricultural systems, and require the development of new and flexible production systems. The solution or mitigation of these changing and multiple problems requires continual adaptation and optimization of agricultural systems, using a quantitative systems approach integrated with field research. The process-level models of agricultural systems, based on synthesis and quantification of available interdisciplinary knowledge, provide the systems approach for evaluating and optimizing the effects of varying management practices, crops, soils, water, and climate to attain sustainable production and maintain environmental quality. Fortunately, the new electronic technologies can provide a vast amount of real-time dynamic information regarding crop and soil conditions via remote sensing with satellites or proximal sensing with ground-based instruments. System models can (and are essential to) assimilate this information to further enhance site-specific management. Models can serve as an evolving theoretical backbone of complex agricultural system research and information transfer to policy makers and farm managers to maintain food security and environmental quality.

System modeling has been a vital step in many scientific disciplines. We would not have gone to the moon successfully without the combined use of knowledge, good data, and computer models. In designing automobiles and airplanes, computer models of the system are increasingly replacing the scaled physical models of the past. Models have also been used extensively in designing and managing water resource reservoirs and distribution systems, and in analyzing waste disposal sites. However, a lot more work is needed to bring agricultural system models to the level of physics and hydraulic system models and to enhance their structure and usability. Agricultural system models have matured enough that, with some good data to serve as reference, they can be used for many practical applications in research and management (Jones *et al.*, 2003; Ahuja *et al.*, 2002; Matthews and Stephens, 2002). The effect of management practices of tillage or no-tillage, different crops and varieties, crop rotations, fertilizers and manures, water application levels, and tile drainage on

production and water quality can now be modeled (Ma *et al.*, 2000; Andales *et al.*, 2003; Saseendran *et al.*, 2005). Their integration with field research will expose knowledge or conceptual gaps in the models that will then be filled with new research. In a Dutch publication, 'Method in Our Madness' International Service for National Agricultural Research (ISNAR), 2004, a case is made for applying modeling tools and processes in planning and implementation of natural resources research and making sense of the vast amount of data. The CGIAR Science Council (2005) noted in their Research Priorities: "Modeling and the ability to combine data from different sources, promises to revolutionize understanding of processes affecting management of natural resources. Thanks to strategic accumulation of data, tools, and modeling resources in the coming decade, one can expect the development of a more predictive approach to agriculture." Integration of field research with system models has the potential to significantly enhance efficiency of agricultural research and raise agricultural science and technology to a higher level, leading to improved production and protection of the environment.

Over the past few decades, many models have been developed to address the same agricultural issue with slightly different objectives. Most, if not all, are fit for the purpose they were developed. Therefore, it is difficult to select one model for a given problem, without going into details of the model components. The purpose of this article is not to give such details of the models that the users can obtain on their own, but to give examples of model applications that make a compelling case that models are important tools that can be used to evaluate and manage the environment and food security. The examples pertain to three critical resource areas: (1) water quality, a major environment issue; (2) water quantity, a major emerging issue, important to both environmental quality and food security; and (3) projecting climate-change effects and identifying adaptation and mitigation strategies for both the environment and food security.

Model Applications to Manage Nitrogen for Crop Production and Water Quality

The use of system models can greatly help N management to maintain or improve crop yields without detrimental environmental impacts, even though N is the most difficult component to simulate with models because of the interactions among several components and the fate of N in soil: plant N uptake, mineralization of organic soil N, nitrification, denitrifcation, ammonia volatilization, NO and N_2O emissions, N fixation, and N movement with soil water. All system models with a plant growth component have the capability of simulating N fate in an agricultural system, but with different levels of detail for each N process. Correct simulation of plant N uptake has been identified as a crucial process in determining N fate in the environment (Ma *et al.*, 2007). Most models can simulate crop response to N application as well as N leaching under different N treatments adequately. A wide range of agricultural management practices to help reduce N pollution of surface and groundwater can also be simulated well. These practices include: optimizing rate and timing of N applications, winter cover crop, controlled subsurface (tile) drainage, nitrification inhibitors, and buffer strips. The main agricultural management practices that result in N pollution of groundwater are N fertilizer and manure applications.

Minimizing Nitrogen Loss to Subsurface Drainage (Tile Flow)

In the Midwest, USA, N loss to subsurface (tile) drainage contaminates streams that feed the Mississippi River and causes hypoxia (lack of oxygen for the fish). Considerable research has been conducted by the United States Department of Agriculture, Agricultural Research Service, and the State universities in the region on management practices to minimize this pollution, including degree of tillage, crop rotations, and timing and rates of manure versus fertilizer applications. One example is a comprehensive study at Nashua, IA. **Figure 1** presents the synthesis and quantification of 14 years of data at Nashua, using RZWQM2 (the enhanced Root Zone Water Quality Model), for corn and soybean yields, annual tile drainage flows, N in tile flow, and the weighted average N concentration in tile flow (Ma *et al.*, 2007). The data represented values averaged over multiple plots and a number of management practices for a number of years. Very high spatial variability of the tile flow, caused by unknown lateral groundwater flow below the tiles, was calibrated for each plot. Individual plot and management simulation results were within the variation of the observed data (Ma *et al.*, 2007). The results in **Figure 1** show a good synthesis of the overall data. On the basis of these results, Ma *et al.* (2007) used the model to develop a chart on the effects of different management practices on N leaching in tile flow as a guide to minimizing leaching while maintaining production for corn–soybean cropping systems (**Figure 2**). As shown in **Figure 2**, higher N loss to tile flow was simulated under continuous corn rotation than under corn–soybean rotation due to N applications every year for continuous corn, and under free drainage than under controlled (reduced) drainage. Tillage effects on N loss were not significant.

The research in Iowa further showed that cover crops, such as rye grass or clovers, planted after corn help to remove residual nitrates from the soil profile and thus reduce its leaching to the tile flow (Kaspar *et al.*, 2007). The research also confirmed that reducing tile flow by raising the tile outlet during fall and winter season following corn raises the water table that helps to denitrify nitrate and reduce its leaching (Crabbe *et al.*, 2012). The scientists in Iowa used the field-tested RZWQM2 model to evaluate the effectiveness of cover crops (**Figure 3**) and controlled drainage (**Figure 4**) in reducing nitrate leaching in different parts of the US Midwest to guide on-farm management.

Optimizing Nitrogen Prescriptions

In the past two decades, N management for maximum crop yield as a single goal has changed to maximum crop yield along with minimum N leaching as a double goal. Matching just the right soil N availability with plant N demand is the key to this double goal. For this purpose, split application of N is usually a desirable method, at least when the added cost of application is not a major issue. Other considerations are to

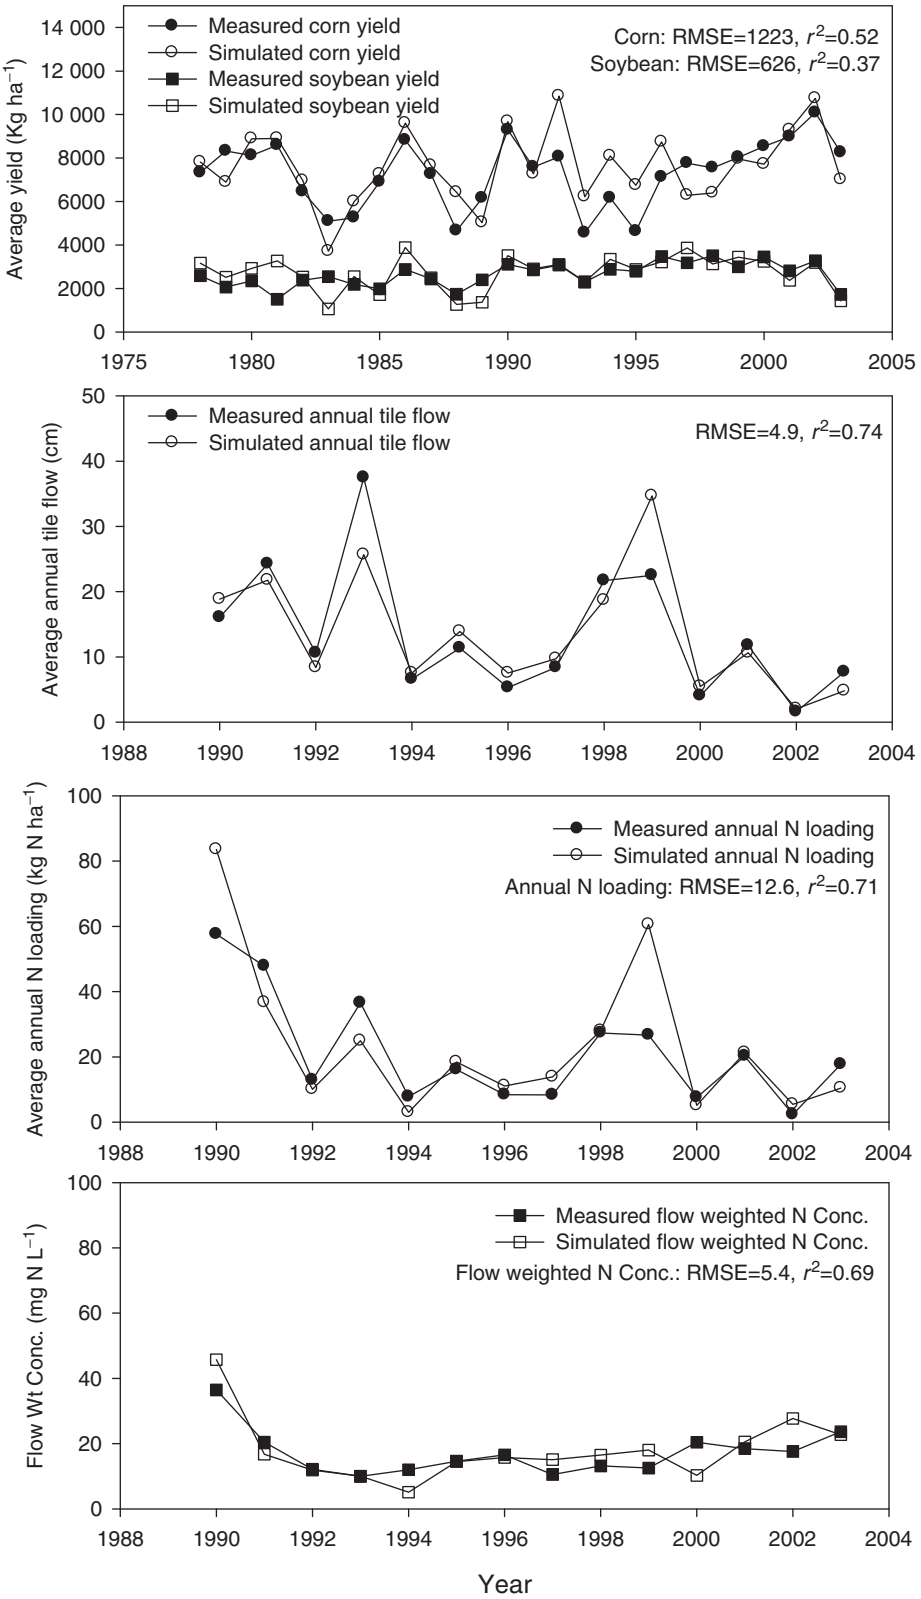

Figure 1 Simulated and measured average corn and soybean yield, yearly tile flow, yearly N loading in tile flow, and flow-weighted N concentration in tile flow across all treatments over 13 years, at Nashua, IA, USA. The results give confidence in the model for identifying best management of N. RMSE, root mean square error; r^2, coefficient of determination. match N application rate with water availability (rainfall or irrigation) (Saseendran *et al.*, 2004) and with other soil conditions that influence productivity (Thorp *et al.*, 2006).

Using the CERES-wheat model calibrated for three growing seasons and five N treatments (0, 28, 56, 84, and 112 kg N ha^{-1}), Saseendran *et al.* (2004) developed probability distribution functions of wheat production using more than 90 years of historical weather data for Akron, CO, USA (**Figure 5**). The model results suggested that an application rate of 56 kg N ha^{-1} was sufficient under dryland conditions for most years in Colorado, without too much residual soil N at harvest (**Figure 5**).

In the North China Plain (NCP), Fang *et al.* (2008) used the calibrated RZWQM2 to investigate the response of long-term crop yield and N leaching to different N application rates (100, 200, and 300 kg N ha^{-1}) and irrigations based on initiation at and recharge to certain levels of field capacity. As shown in **Figure 6**, the highest grain yield was obtained when irrigation was triggered at 50% field capacity and recharged to 70% field capacity at 200 kg N ha^{-1} per crop, indicating that N application rate at approximately 200 kg N ha^{-1} per crop was generally sufficient to obtain high crop yields in the wheat–maize double-cropping system in the region. Compared with 300 kg N ha^{-1} application rates, nitrate-N leaching at 200 kg N ha^{-1} per crop application rate was reduced by 63% for the wheat seasons, and by 60% for the maize seasons (**Figure 6**). However, constrained by limited water resources in the region, the current irrigation amounts are less than 300 mm for wheat, and little or no irrigation for maize. This amount of available water can only sustain an autoirrigation triggered at 40% and recharged to 60% field capacity and produce a potential wheat yield of 76% and a potential maize yield of 86%. At this irrigation level, the N application rate should be reduced to between 100 and 200 kg N ha^{-1} for wheat, to match the limited available irrigation water resource in the region for efficient use of N and water and minimal nitrate-N leaching loss (**Figure 6**). For maize, irrigation was not necessary due to adequate rainfall, and 100 kg N ha^{-1} per crop application rates are reasonable considering the high risk of nitrate-N leaching potential (**Figure 6**).

Thorp *et al.* (2006) used the calibrated CERES-Maize model to prescribe N rate for a heterogeneous field in Iowa, USA, using long-term weather data (37 years) to study maize production and N leaching risks at different levels of precision nitrogen (N) management. The value in using long weather records could be expanded to discuss risk assessments of decision making and probabilities of 'success.' Nitrogen was applied uniformly in the spring; for each rate of application, the field was divided into 100 grid cells and the model was run for each cell for 37 years. To maximize farmers' net returns, an average of 56.2 kg N ha^{-1} overall grid cells was left in the soil as residual N, which was subjected to leaching (**Figure 7**). To achieve an average residual soil N at harvest under 40 kg ha^{-1} in 80% of the growing seasons, the producer's opportunity

Journal of Soil and Water Conservation.

cost that reduced the maximum return was estimated to be US \$48.12 ha^{-1} (Figure 8).

Model Applications to Optimize Water Use in Crop Production

The use of irrigation system models to estimate crop yield responses to water in general and to allocate limited water resources is widely documented in the literature. The use of the detailed soil–water–plant growth–climate system models for optimizing the use of available water through optimum rates and times of irrigation application is relatively new, but is improving and making progress.

Optimizing the Use of Limited Water through Irrigation Scheduling

One approach for optimizing limited water is by scheduling irrigation at the right time and in amounts to match the crop–water demand. However, this scheduling will vary from year to year due to variations in timing and amount of rainfall and other weather conditions that determine the crop demand. At any location, the models can be run over a long time period of historical weather conditions to help devise optimum scheduling over this period and assess risks. The value in using long weather records could be expanded to discuss risk assessments of decision making and probabilities of 'success.' Figure 9 shows the evaluation of decision support systems for agrotechnology transfer (DSSAT) version 4.0 CERES-maize model against multiyear experimental data for the response of corn to different water levels at Akron, CO, USA. The model provided a good synthesis of the data. This field-tested model was then used to create a graph of corn yield for different amounts of controlled water applications during the entire growth period to aid optimal management of limited water for three different scenarios, run over 90 years of weather data, at Akron, CO, USA (Saseendran *et al.*, 2008). The initial soil water content at planting was assumed to be what is commonly observed at Akron; the top 30 cm of soil was at field capacity, and deeper depths at half the field capacity. The response to water applications was studied at two N levels, a fixed amount of N (168 kg ha^{-1}) denoted as 'with N stress' and with assumed 'No N stress' in the crop model. The data points in Figure 10 are mean values over 90 years of weather and the vertical bars on the data indicate one standard deviation of simulated points around the mean. The yield

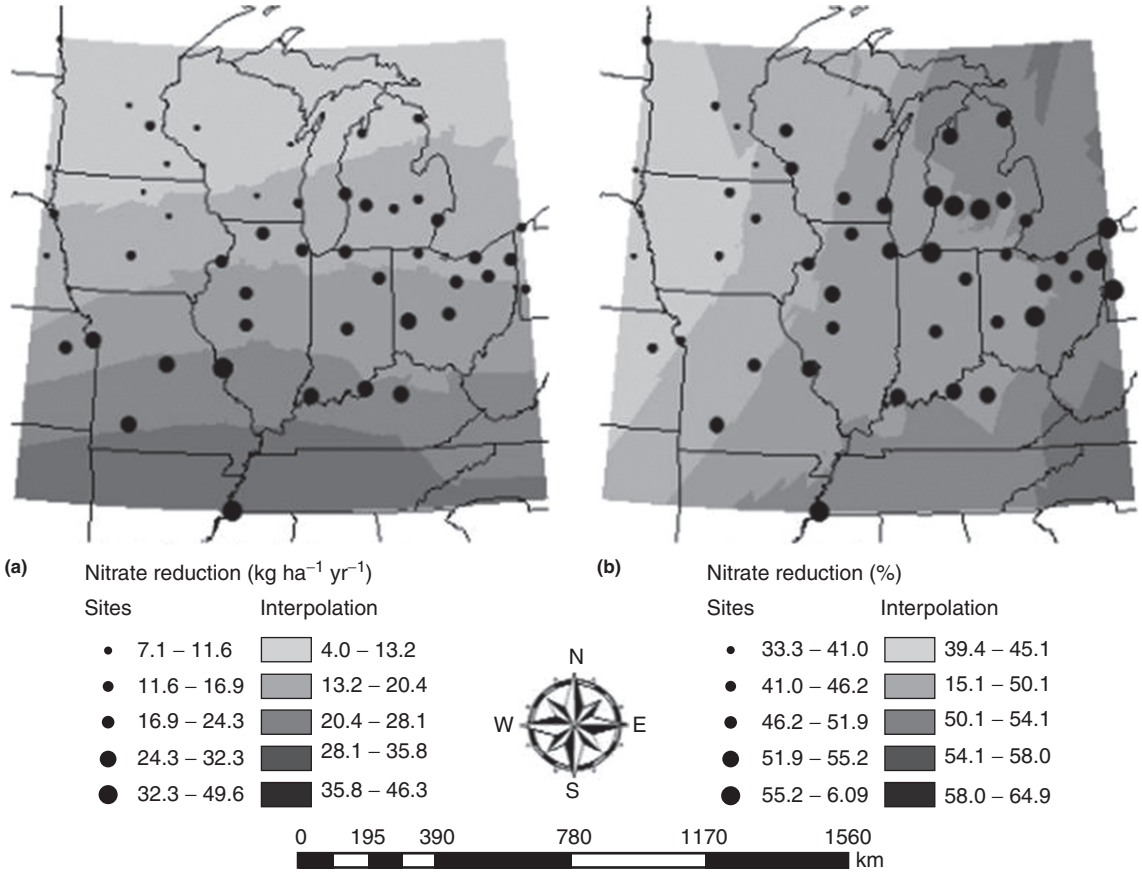

Figure 4 RZWQM2 used to calculate annual nitrate reduction in tile water by 'controlled' drainage in the US Midwest region (kg N ha^{-1} year^{-1}). Reproduced with permission from Thorp, K.R., Jaynes, D.B., Malone, R.W., 2008. Simulating the long-term performance of drainage water management across the Midwestern United States. Transactions of the ASABE 51 (3), 961–976.

increased with water application level, up to a maximum at approximately 400 mm of water application, and started to decrease thereafter due to N leaching in the 'with N stress' treatment, whereas it leveled off with 'No N stress' (Figure 11). In one of the water application scenarios (50%V and 50%R), half of a given total amount of water was applied during the vegetative growth stages and the other half during the reproductive growth stages. In another scenario (20%V and 80%R), the same total amount of water was split in a way that 20% was applied during the vegetative growth stages and 80% during the reproductive stages; in the third scenario, the split was 40% during the vegetative stages and 60% during the reproductive stages. The 20–80 split was the best as an average over the years, although the results depended on weather from year to year, as indicated by the vertical bars. A corresponding graph was generated for nitrogen balance components – plant uptake, leaching below the root zone, and residual in soil, at different irrigation levels for each scenario (Figure 11).

The N uptake by the crop had the same trend of variation with water levels as the yield in Figure 10. It increased with water level up to a maximum of approximately 400 mm water application, and did not change much thereafter. The N leaching increased mildly with water level up to 400 mm level, and then more rapidly. The residual N left in soil at the end of the growth period decreased with water level. The 20:80 split application of water had the least leaching of N as compared with 50:50 and 40:60 splits. The graph in Figure 11 can be used to optimize the amount of N application with respect to the amount of water available and expected crop yield, instead of applying the same N amount for each year, irrespective of rainfall or irrigation water available. The optimization of N application will save the farmer's input costs and minimize effects on groundwater quality by reducing leaching during the growth period or reducing the residual N subject to leaching during fall and winter. The graphs in Figures 10 and 11 help both research and management for optimizing the use of water and nutrients.

Optimizing Water Productivity of Limited Water by Applying Water at Sensitive Growth Stages and Rationing Water between Crops in China

Fang *et al.* (2010) applied the RZWQM2 model to a double-cropping system (wheat–maize) in the NCP, using historical long-term weather data. They found that a higher wheat yield could be obtained when a single irrigation was applied at the stem extension stage than when it was applied at booting or grain filling stage. These results indicated that the stem extension stage was the most sensitive growth stage of wheat to

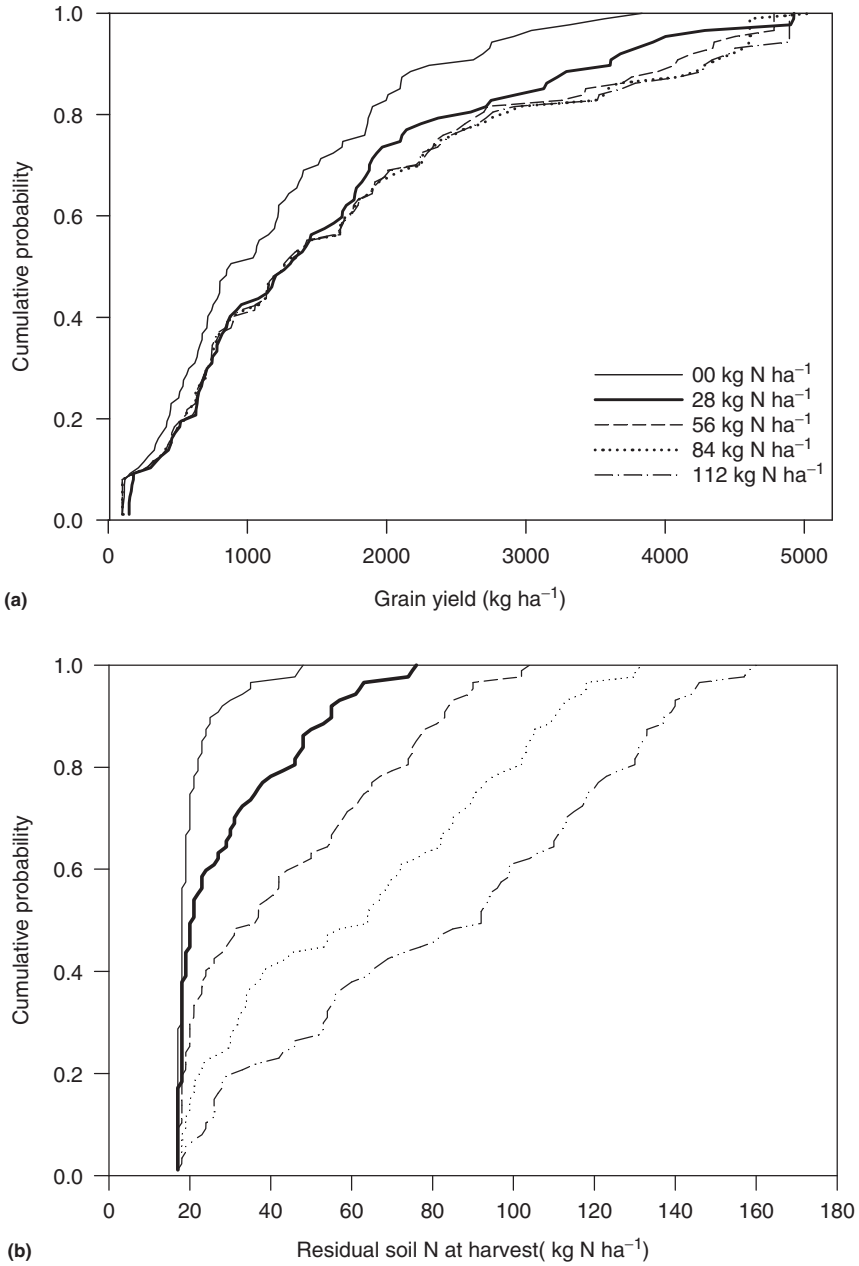

Figure 5 Cumulative probability distribution function plots of winter wheat grain yields and residual soil N at harvest simulated by CERES-wheat model under different N application rates. N was broadcast and the crop was planted every year. Reproduced with permission from Saseendran, S. A., Nielsen, D.C., Ma, L., Ahuja, L.R., Halvorson, A.D., 2004. Modeling nitrogen management effects on a winter wheat cropping system using RZWQM and CERES-wheat. Agronomy Journal 96, 615–630.

water stress. However, in short-term field experiments, the most sensitive stages of wheat to water stresses were extended from stem extension to grain filling stage. Higher crop yield and water-use efficiency (WUE) could be obtained when two irrigations were applied at stem extension and booting stages than applied at other stages. These higher yield and WUE treatments also had lower deep drainage and N leaching. Irrigation for maize was generally unnecessary except when the initial soil water is too low for germination.

Another long-term simulation was designed to optimize the limited water between wheat and maize seasons for high WUE and minimum drainage. Water distribution between the wheat and maize seasons was tested at six ratios: 50:50; 60:40; 70:30; 80:20; 90:10; and 100:0, for each of the four assumed total amounts of water available, applied at different growth stages (Fang *et al.*, 2010). Wheat yields increased linearly with the distribution ratios varying from 50:50 to 100:0 (**Figure 12**), whereas maize yield decreased slightly. The WUE of wheat increased with the irrigation ratio from 50:50 to 100:0 at 100 and 150 mm available water, whereas at 200 and 250 mm available water level, WUE reached the highest values at ratios of 80:20 and 60:40, respectively. For maize, WUE

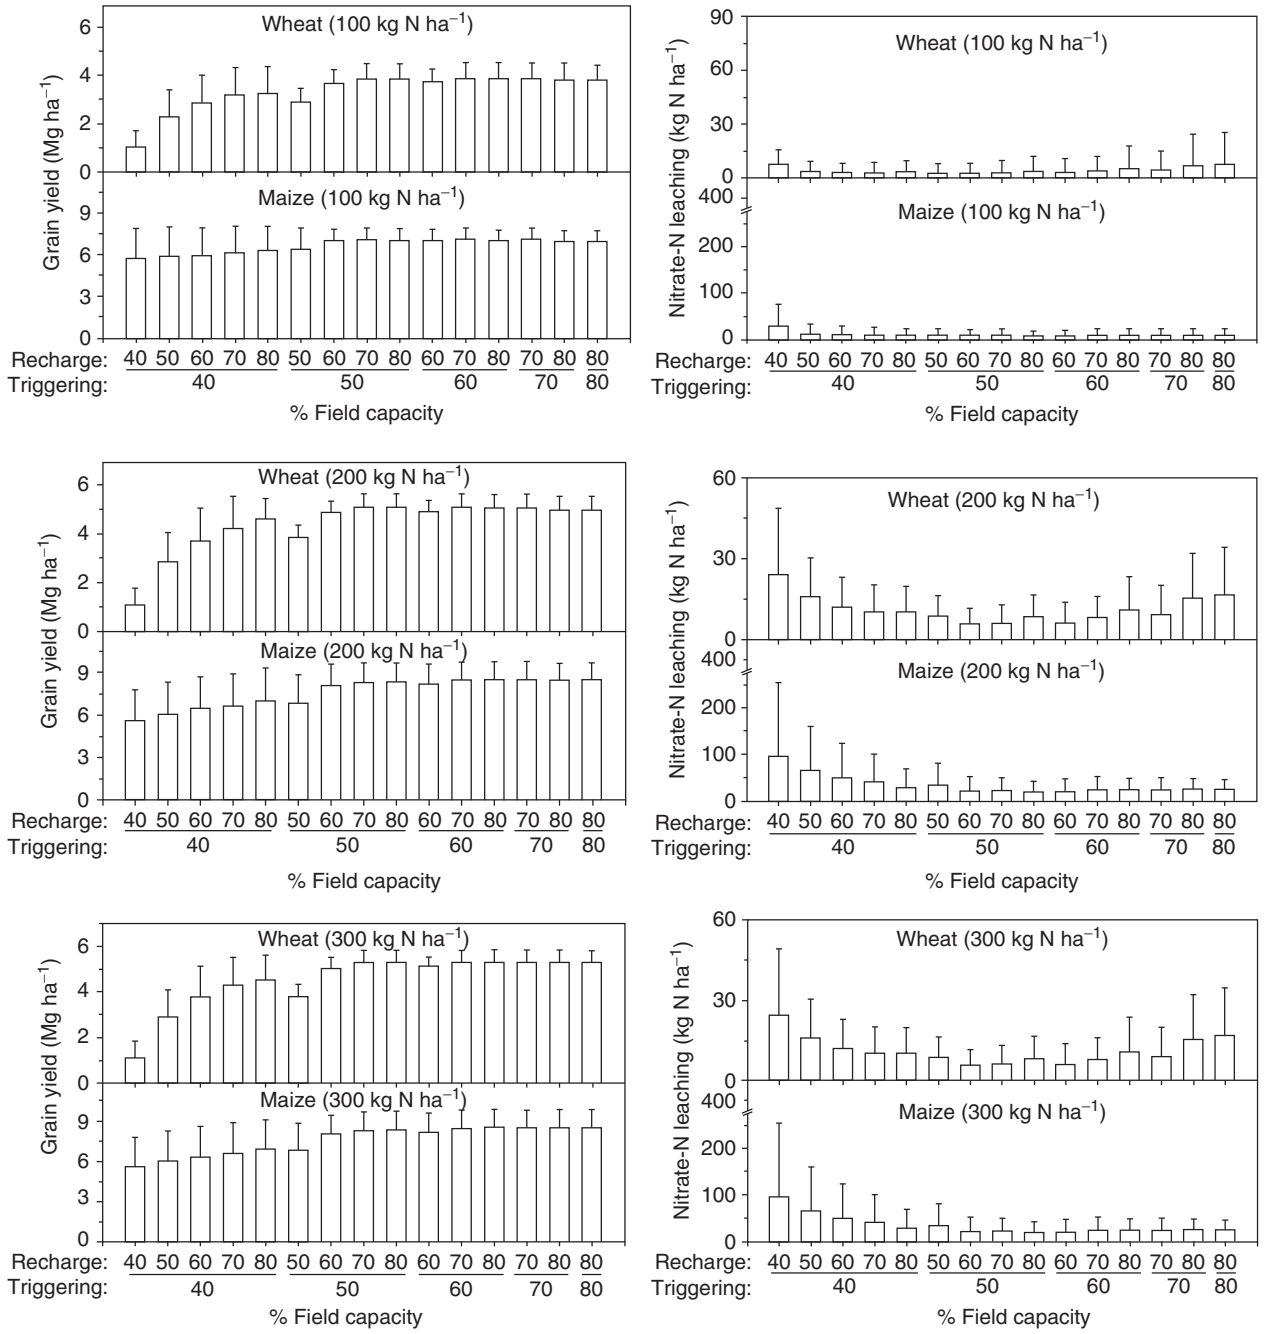

Figure 6 Average grain yields and nitrate-N leaching across seasons under irrigations triggered at varying levels of % field capacity (FC) and stopped after root zone recharge to selected levels of %FC and at different N application rates (100, 200, 300 kg N ha^{-1} per season) simulated by RZWQM2 from 1961 to 1998. Bars indicate +1 standard derivation across 38 years of simulation (1961–98). Reproduced with permission from Fang, Q., Ma, L., Yu, Q., *et al.*, 2008. Modeling nitrogen and water management effects in a wheat-maize double-cropping system. Journal of Environmental Quality 37, 2232–2242.

increased slightly with the irrigation ratio varying from 50:50 to 100:0 and with a decrease in available water from 250 mm to 100 mm (Figure 12).

Combining both wheat and maize seasons in a year, wheat and maize yields and WUE were maximum at the distribution ratio of 80:20 at both 200 and 250 mm available water. Drainage and N leaching were the lowest for the distribution ratio of 80:20 at 100, 150, and 250 mm available water and the lowest for the distribution ratio of 90:10 at 200 mm available water. Therefore, it can be concluded that the most reasonable distribution ratio for available water between the wheat season and the maize season was 80:20 at the four limited available water levels to obtain the highest crop yield and WUE and the lowest water drainage.

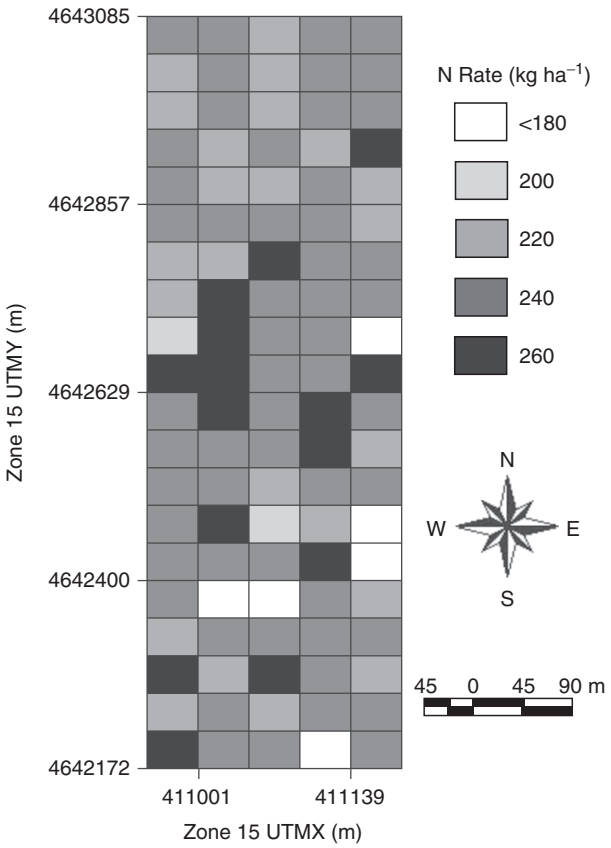

Figure 7 Nitrogen prescription for maximum farmer's profit in a variable land area that left an average 56.2 kg N ha^{-1} of unused N at harvest in IA, USA. Methodology to link production and environmental risks of precision nitrogen management strategies in corn. Agricultural Systems 89, 272–298.

Better Water-Use Efficiency through Crop Rotations

The models can be used to help maximize precipitation use efficiency by more intensive cropping, such as adding an appropriate summer crop in the traditional dryland (rainfed) wheat–fallow rotation in the Great Plains of the USA. However, the choice of the summer crop will vary from year to year depending on the soil water stored at planting and the anticipated rainfall during the growing season. The models can be used to determine the choice of the summer in relation to soil water planting over long-term weather conditions at any given location. Figure 13 shows RZWQM2 synthesis of dryland crop production data for four different crop rotations at Akron, CO, USA. The tested model was then used to evaluate the performance of different summer crops for rotation with the primary crop of winter wheat over 97 years of weather conditions, at four different levels of plant available soil water (PAW) during planting of these crops. Figure 14 gives the mean and variance of net return from five different crops at each level of PAW. The forage crops give higher returns than the corn and canola crops at all levels of PAW at the prevailing crop prices at the time of the study. This graph serves as a guide to choose the summer crop in any year based on known PAW and crop prices.

Better Crop Selection and Deficit Irrigation

Figure 15 shows a RZWQM model synthesis of corn response to different levels of limited irrigation at Greeley, CO, USA. The tested model was then used to develop long-term average Crop Water Production Functions (yield vs. water consumed and water applied) for several counties of Colorado (Figure 16). Similar water production functions were obtained for other crops. The authors have used these functions to develop a 'Colorado Water Optimizer' to help farmers with decisions on the best use of limited irrigation water in Colorado, including the options of selecting which crops to irrigate, deficit irrigation of crops, areas irrigated, and leasing water to the Denver municipality or other urban uses.

Evaluating Agricultural Systems and Management Effects on Greenhouse Gas Emissions

In general, agriculture (this excludes emissions from livestock) is a minor to moderate source of greenhouse gas (GHG) emissions. It is generally accepted that N fertilizer is a major contributor to GHG production in an agricultural land. The emission of GHGs from agricultural land, mainly CO_2, N_2O, and CH_4, shows high spatial and temporal variability, associated with agricultural management practices (fertilizer and irrigation application, tillage, cover crop, and cropping system), as well as climate and soil conditions (Liebig *et al.*, 2005; Snyder *et al.*, 2009). Various models have been explored to simulate GHG emissions from soil at laboratory, field, and regional scales (Chen *et al.*, 2008; Pattey *et al.*, 2007). The process-based field-scale models, such as denitrification–decomposition (DNDC; Li *et al.*, 1992), DAY CENTURY (DAYCENT) (Parton *et al.*, 1998), agricultural production systems simulator (APSIM; Probert *et al.*, 1998), and water and nitrogen management model (WNMM; Li *et al.*, 2007), have been most widely used to quantify the effect of alternative agricultural managements on GHG emissions across different time and spatial scales.

The DNDC model has been applied worldwide for GHG emission simulation and identifying management strategies for mitigation. In the United States, soil tillage and fertilizer use were the most important farming practices contributing to N_2O emissions at the national scale; even manure applications to corn increased N_2O emissions in Iowa, although it enhanced carbon storage in soils (Li *et al.*, 1996). Farahbakhshazad *et al.* (2008) concluded that no-till practice slightly increased N_2O emissions, but increasing fertilizer application depth with nitrification inhibitor substantially reduced N_2O emissions in central Iowa. However, in a wheat–maize cropping system in North China, manure amendment or crop residue incorporation mitigated GHG emissions from the cropping system (Li *et al.*, 2010). Wang *et al.* (2011) also concluded that residue return was a more efficient method of mitigating GHG emission than decreasing fertilizer N application rate in Northwestern China. However, in an agricultural

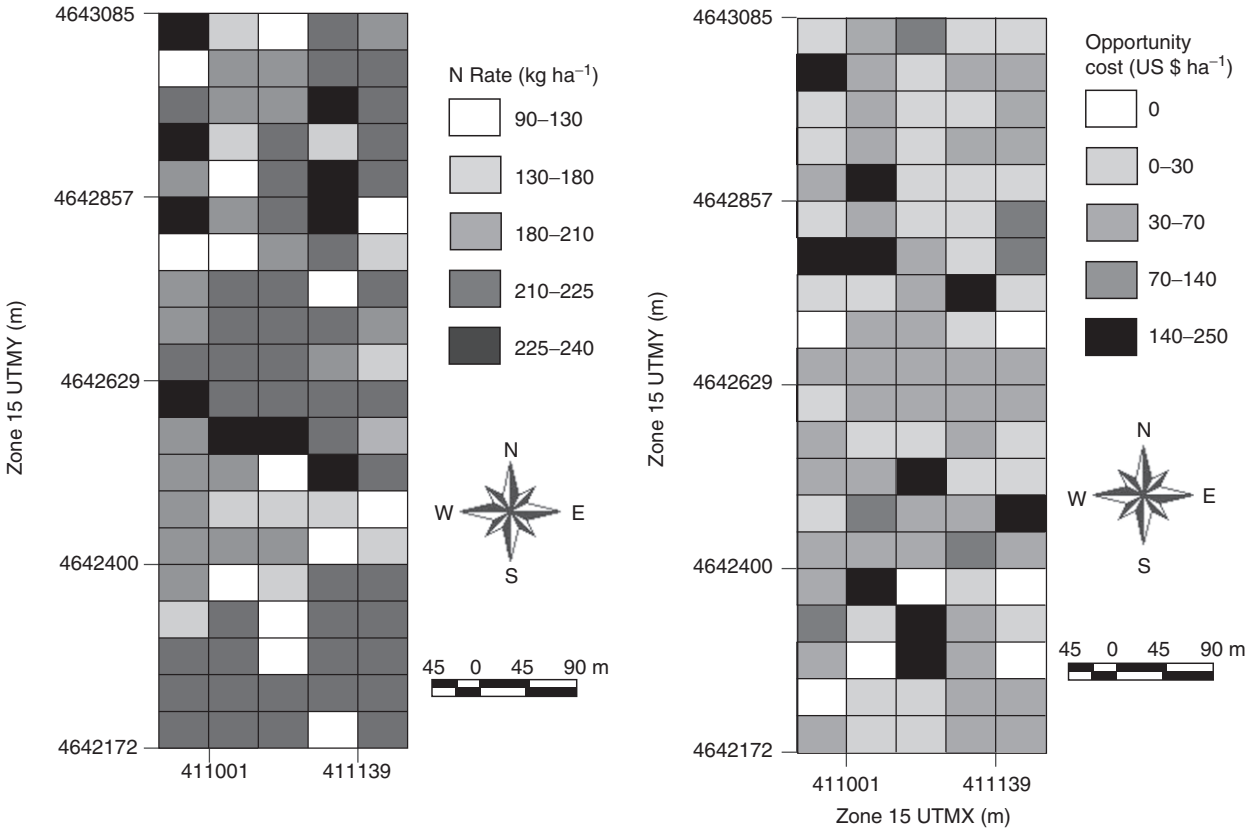

Figure 8 N rate and opportunity cost for leaving less than 40 kg N ha^{-1} of unused N in the soil 80% of the time. Opportunity cost is the additional cost that reduces the maximum profit. Use of crop simulation models to evaluate limited irrigation management options for corn in a semiarid environment. Water Resources Research 44, W00E02. doi:10.1029/2007WR006181.

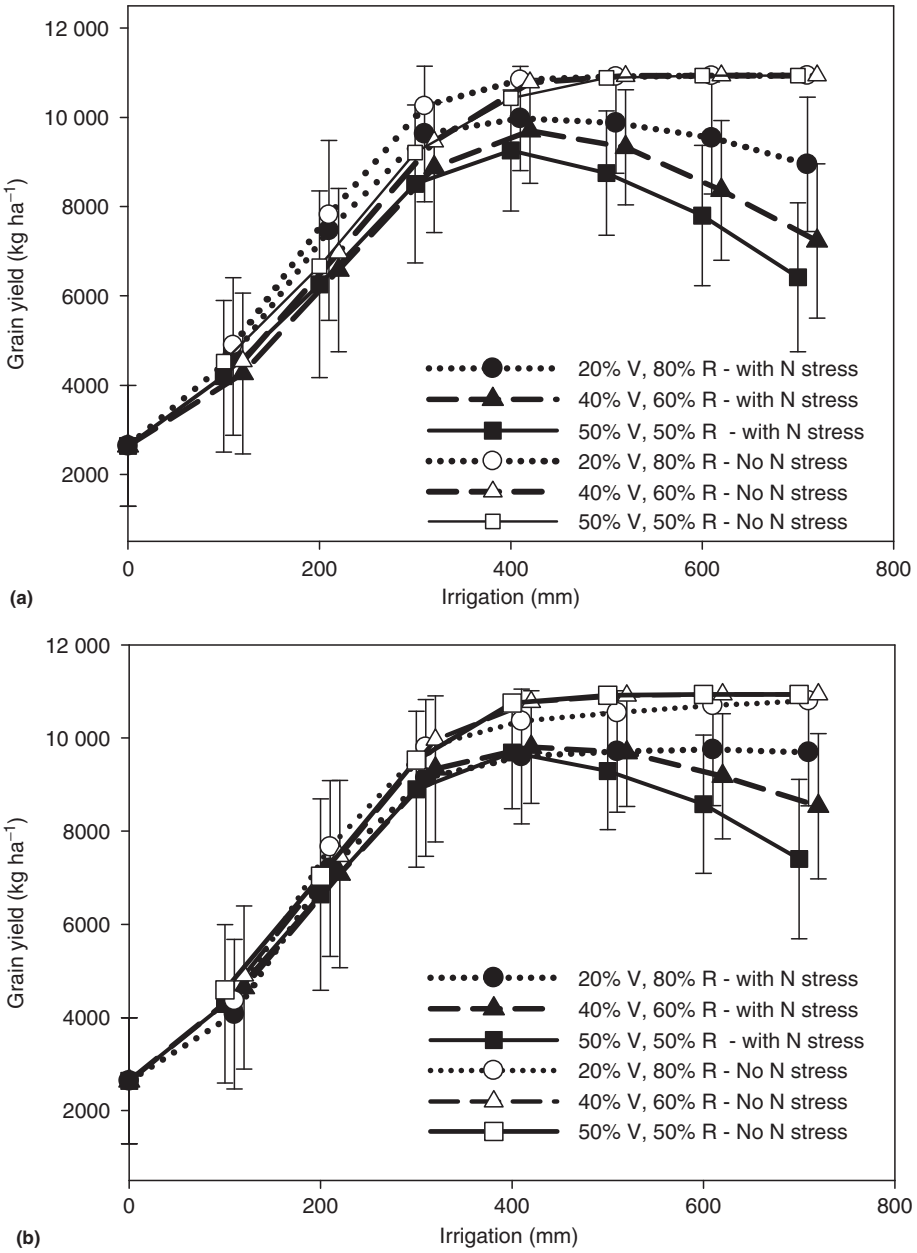

Figure 10 Simulated grain yield response to 100–700 mm irrigations (gross irrigation), split between vegetative and reproductive stages at 20:80, 40:60, and 50:50 with (a) 22 June and (b) 15 July as cutoff dates differentiating between growth stages for corn grown at Akron, CO. Distribution of average seasonal potential evapotranspiration demand between the vegetative and reproductive growth stages was (a) 38:62 and (b) 55:45. Error bars represent one standard deviation from the mean. Deviations of grain yields from the mean value were due to variation in rainfall, temperature, and solar irradiance during the crop growth period from 1912 to 2005. Average crop season rainfall was 284 mm. Reproduced with permission from Saseendran, S.A., Ahuja, L.R., Nielsen, D.C., Trout, T., Ma, L., 2008. Use of crop simulation models to evaluate limited irrigation management options for corn in a semiarid environment. Water Resources Research 44, W00E02. doi:10.1029/2007WR006181.

freeze zone in North China, Ouyang *et al.* (2012) observed that both manure amendment and N fertilizer enhanced the global warming potential (GWP), but the return of residue to the soil was a win-win solution for soil carbon and GWP. In Ireland, Lugato *et al.* (2010) simulated an accumulation of 1100 kg C ha^{-1} of soil organic carbon and lower N_2O emission with conversion of conventional to minimum tillage for maize, whereas residue removal led to high soil C depletion and GHG emissions. Rafique *et al.* (2011) simulated a $\pm$9% and $\pm$17% change in N_2O emissions under $\pm$50 kg inorganic N and slurry N application rate, respectively, which was much lower than the estimated change of 50% based on Intergovernmental Panel on Climate Change (IPCC) default emission factor (EF).

The DAYCENT model is another popular model applied for GHG emission simulations. In the Great Plains, USA, Del Grosso *et al.* (2002) observed that the dryland soils and cropping systems are net sources of GHGs, although they can

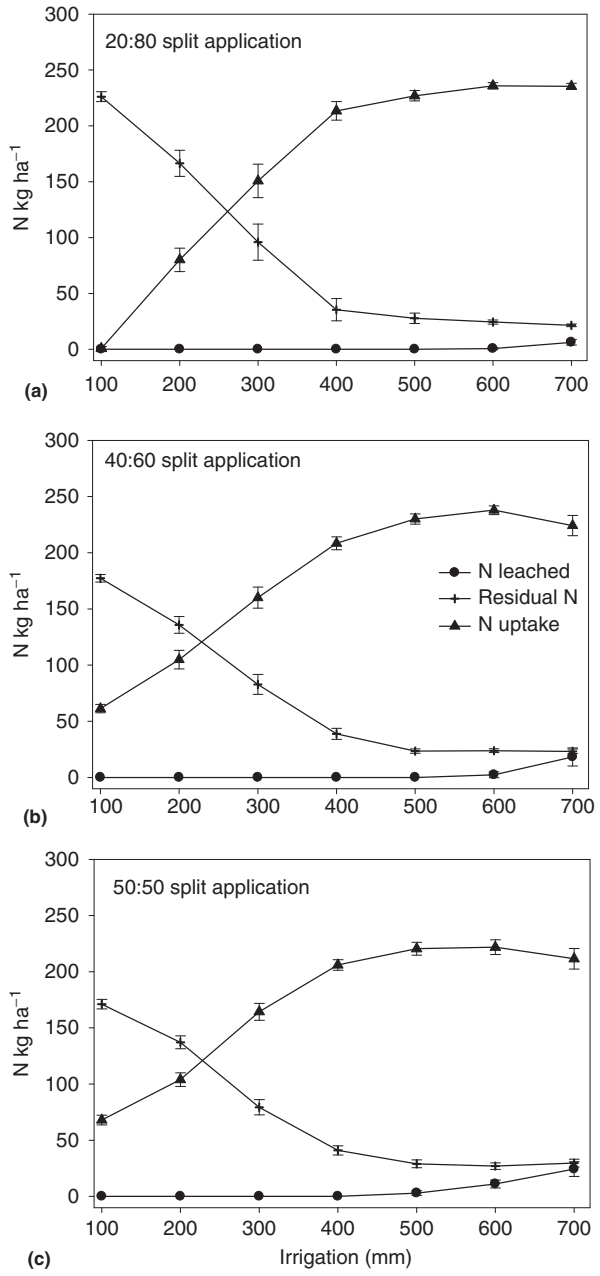

Figure 11 Model-generated N balance components at different levels of water application for corn averaged over 90 years of weather data at Akron, CO, for each scenario of water distribution between growth stages corresponding to the data in **Figure 10** (22 June as the cutoff date differentiating between the growth stages). Again, the vertical bars indicate one standard deviation around the mean values. V, vegetative growth stage; R, reproductive growth stage. Reproduced with permission from Saseendran, S.A., Ahuja, L.R., Nielsen, D.C., Trout, T., Ma, L., 2008. Use of crop simulation models to evaluate limited irrigation management options for corn in a semiarid environment. Water Resources Research 44, W00E02. doi:10.1029/2007WR006181.

be significantly reduced by practicing no-till. By dividing the United States to five regions (**Table 1**), Del Grosso *et al.* (2005) simulated N_2O emission for each region and for each major crop with DAYCENT model and using the EF from the IPCC (**Figure 17**). The biggest GHG emission was from the Central Region that had the biggest area and more fertilizer applications. Results also showed higher N_2O emission from corn and soybean fields compared to cotton, alfalfa, and wheat. Current management practices (1991–2000) produced much more N_2O than pre-1940 management (1921–30) or native vegetation (1591–1600) (**Figure 17**). However, conversion into no-tillage could mitigate 20% of agricultural GHG emissions in the United States (Del Grosso *et al.*, 2005). In a later study at the global scale, they found that nitrification inhibitors led to 10% reduction in N losses, but when combined with no-till, it resulted in 50% reduction in GHG emissions and 7% increase in crop yield (Del Grosso *et al.*, 2009). In California's Central Valley, the model results showed that organic practices had the greatest potential for soil GHG flux reduction, followed by cover cropping and conservation tillage (De Gryze *et al.*, 2010). In another similar simulation study (De Gryze *et al.*, 2011), the results showed that combining various mitigation practices (conservation tillage, winter cover cropping, manure application, and reduced N fertilizer input) led to larger reductions in GHG emissions than the sum of the reductions from individual practices. The combination of winter cover cropping with manure application was particularly efficient in reducing GHG emissions.

These model applications showed complex effects of these various alternative farming management practices across different climate and soil conditions. Process-based models showed great potential for quantifying these complex effects of alternative management on GHG emissions across different soil and climate conditions. However, we need a better understanding of the underlying factors that cause these variations across soils, climates, and management; and identify strategies for mitigation under those conditions. There is a particular need to quantify GHG emissions due to nitrification and denitrification processes. In general, the soil–water–crop management practices that increase crop biomass growth and generate higher carbon residue can potentially increase soil carbon storage to counteract the CO_2 and CHG buildup in the atmosphere (Smith *et al.*, 2007).

Climate-Change Effects on Environment and Crop Production

The likely doubling of atmospheric CO_2 will cause considerable global warming within the twenty-first century. This will very likely increase droughts, heat waves, and floods, and very likely affect agriculture through changes in plant growth rates, evapotranspiration (ET), plant–water relations, plant litter composition, and nitrogen demands (Morgan *et al.*, 2004; Long *et al.*, 2006). The effect of climate change on agriculture at any location will depend on the current climate, soil–plant interactions, the magnitude of change and responses of the crops, and location-specific management. Numerous modeling studies have been conducted to evaluate climate-change effects on crop production in different regions of the globe (Hillel and Rosenzweig, 2011, 2012). Free-air CO_2 enrichment (FACE) experiments, combined more recently with temperature treatment, provide direct evidence of climate-change

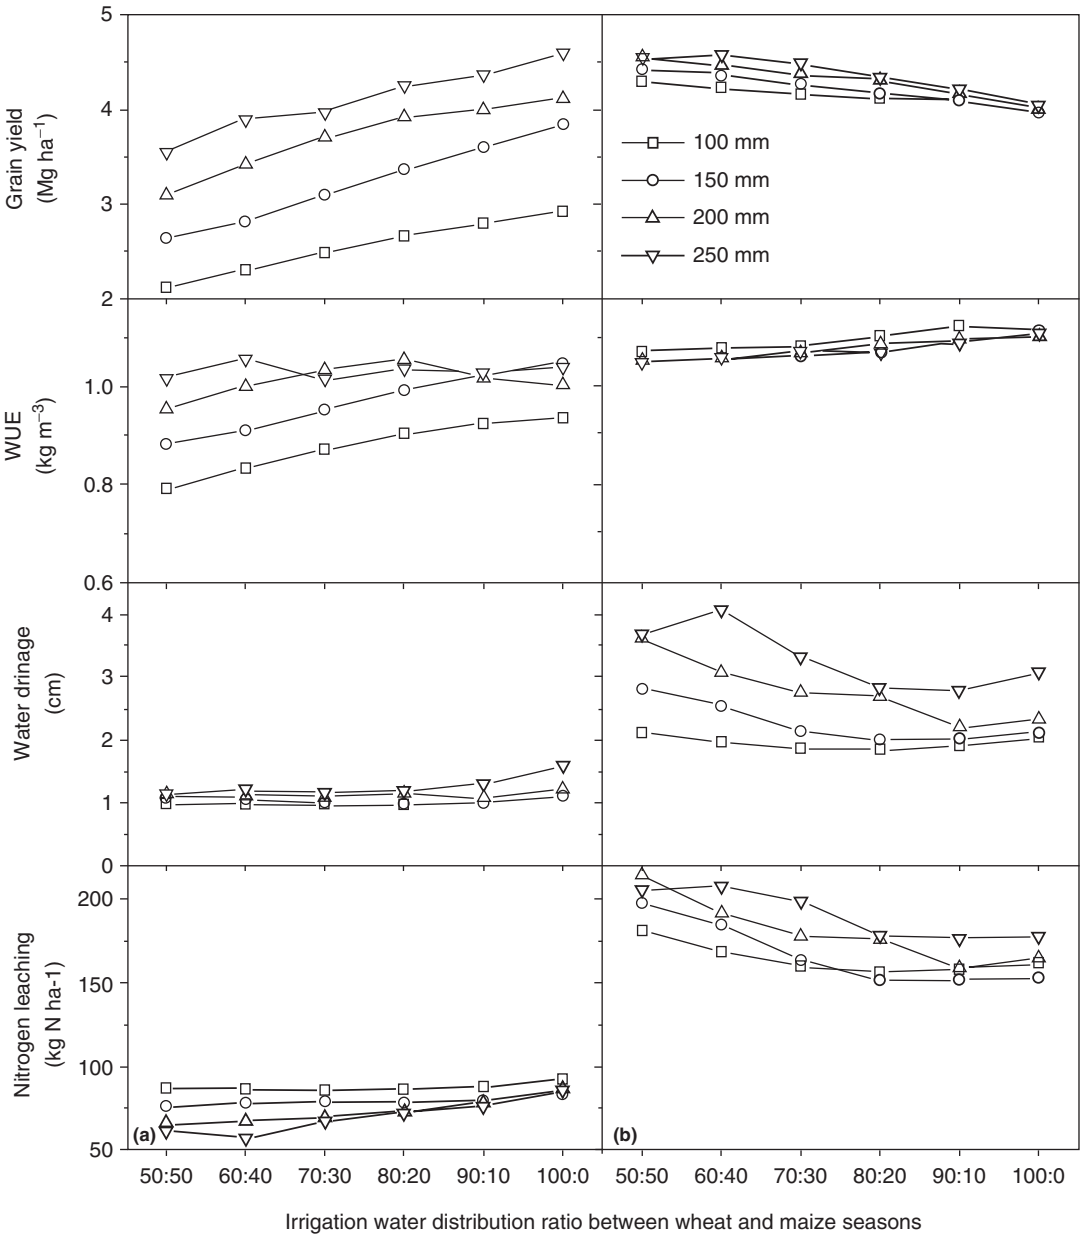

Figure 12 Grain yield, water-use efficiency (WUE), water drainage, and N leaching for wheat (a) and maize (b) seasons at the four limited available water levels (100 mm, –□–; 150 mm, –○–; 200 mm, –△–; 250 mm, –▽–), split between wheat and maize seasons at various ratios. Simulations were made with RZWQM2 from 1961 to 1999. Water was applied at selected growth stages for each crop. Reproduced with permission from Fang, Q.X., Ma, L., Yu, Q., *et al.*, 2010. Irrigation strategies to improve the water use efficiency of wheat-maize double cropping systems in North China Plain. Agricultural Water Management 97, 1165–1174.

effects on crop production in the short term (Kimball *et al.*, 1999, 2002).

Evaluating Future Climate-Change Effects on Crop Production in Specific Regions

Using RZWQM2, Ko *et al.* (2010) were able to simulate the effect of elevated CO_2 on spring wheat growth under various water and N levels from 1992 to 1997 for the FACE study in Maricopa, AZ, USA. With projected CO_2 concentration of 550 ppm in the year 2050 and projected weather from 16 general circulation models (GCMs), they found that the beneficial effects of elevated CO_2 on crop growth were counterbalanced by temperature increase for most of the GCM-projected scenarios. However, precipitation had little effect on crop growth due to smaller projected changes. In a later study to evaluate climate-change impact on dryland crop rotations of wheat–fallow, wheat–corn–fallow, and wheat–corn–millet in the Central Great Plains, USA, Ko *et al.* (2012) found that wheat yield decreased under the projected climate-change scenarios, but not significantly. However, corn and millet

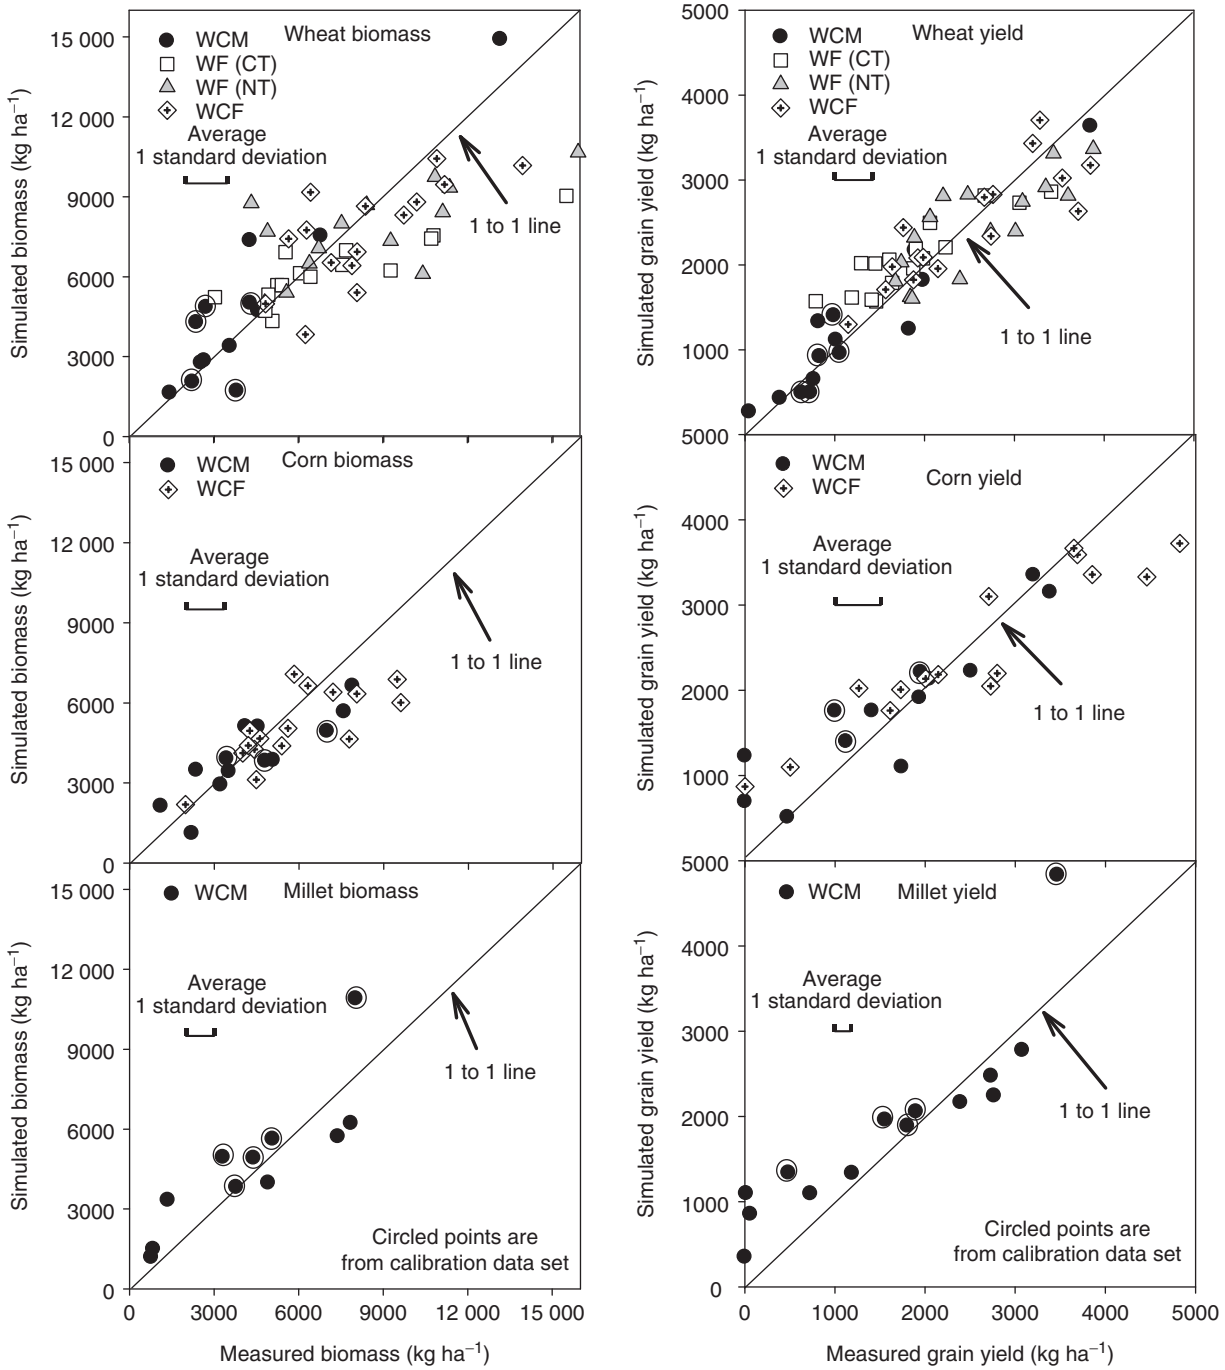

Figure 13 RZWQM modeling of 17–18 years data for biomass and grain yield for wheat, corn, and millet crops from four different rotations at Akron, CO, USA. WCM, wheat–corn–millet; WF, wheat–fallow; and WCF, wheat–corn–fallow. Reproduced with permission from Saseendran, S.A., Nielsen, D.C., Ma, L., Ahuja, L.R., Vigil, M.F., 2010. Simulating alternative dryland rotational cropping systems in the central Great Plains with RZWQM2. Agronomy Journal 102, 1521–1534.

yields decreased significantly, so did the transpiration. Overall, the projected negative effects of rising temperature on crop production dominated over any positive impacts of atmospheric CO_2 increases in these dryland cropping systems (Ko *et al.*, 2012). A similar conclusion was drawn by Islam *et al.* (2012) with irrigated corn, who found that the yield decrease was linearly related to the shortening of the growing period caused by increased temperature.

Chavas *et al.* (2009) examined the potential climate-change impacts on the productivity of canola, corn, potato, rice, and winter wheat in Eastern China. The historical baseline (1961–90) climate and climate change obtained from the

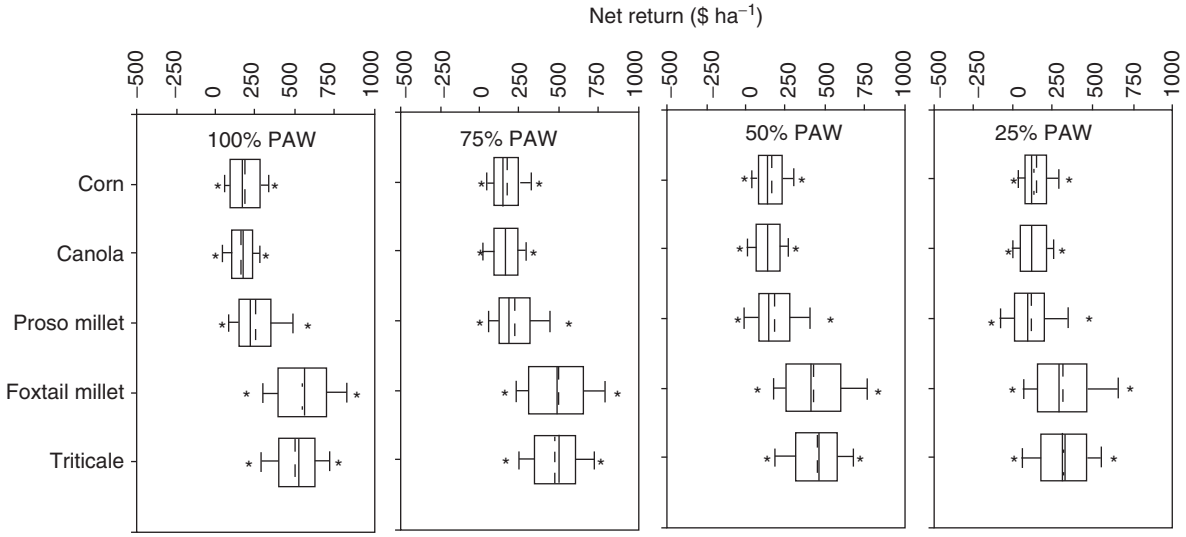

Figure 14 Validated RZWQM2 with long-term weather data generated this graph of Net Return for five summer crops (corn, canola, proso millet, foxtail millet, and triticale), as a guide for summer crop selection in a wheat–summer crop–fallow rotation in Colorado and the Central Great Plains, based on100, 75, 50, and 100% plant available water (PAW) at planting. Reproduced with permission from Saseendran, S.A., Nielsen, D.C., Ahuja, L.R., Ma, L., Lyon, D.J., 2013. Simulated yield and profitability of five potential crops for intensifying the dryland wheat-fallow production system. Agricultural Water Management 116, 175–192.

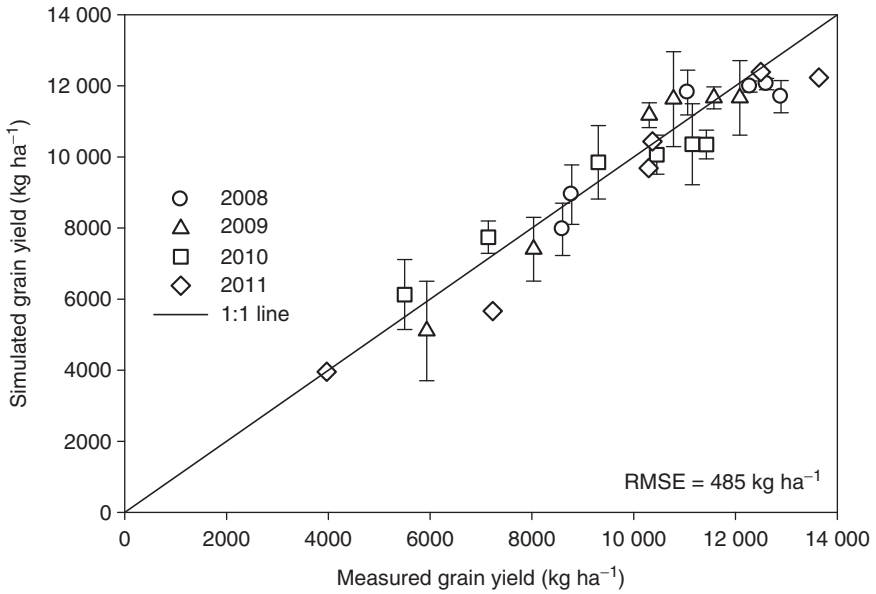

Figure 15 Comparisons of simulated and measured corn grain yields in the limited irrigation trials conducted at Greeley, CO, from 2008 to 2010. RMSE, root mean square error. Reproduced with permission from Saseendran, S.A., Nielsen, D.C., Ahuja, L.R., Ma, L., Lyon, D.J., 2013. Simulated yield and profitability of five potential crops for intensifying the dryland wheat-fallow production system. Agricultural Water Management 116, 175–192.

International Centre for Theoretical Physics RegCM3 regional climate model for future (2071–2100) periods under A2 emission scenario conditions of the Intergovernmental Panel on Climate Change, Special Report on Emission Scenario (Intergovernmental Panel on Climate Change (IPCC), 2007) were used as input for the environmental policy integrated climate agroecosystem simulation model. Results have indicated that in key present-day crop production zones, corn and winter wheat yields may increase substantially, potato yields decline substantially, canola yields remain relatively constant, and rice yields may decrease inland and increase toward the coast. Mo *et al.* (2009) used the vegetation interface processes model to evaluate responses of winter wheat–summer maize double-cropping system in the NCP to future climate scenarios of twenty-first century projected by the HadCM3 GCM under A2 and B1 emission scenarios. Results have indicated that the winter wheat yield will significantly increase with a maximum increase of 19% occurring under the A2 emission scenario

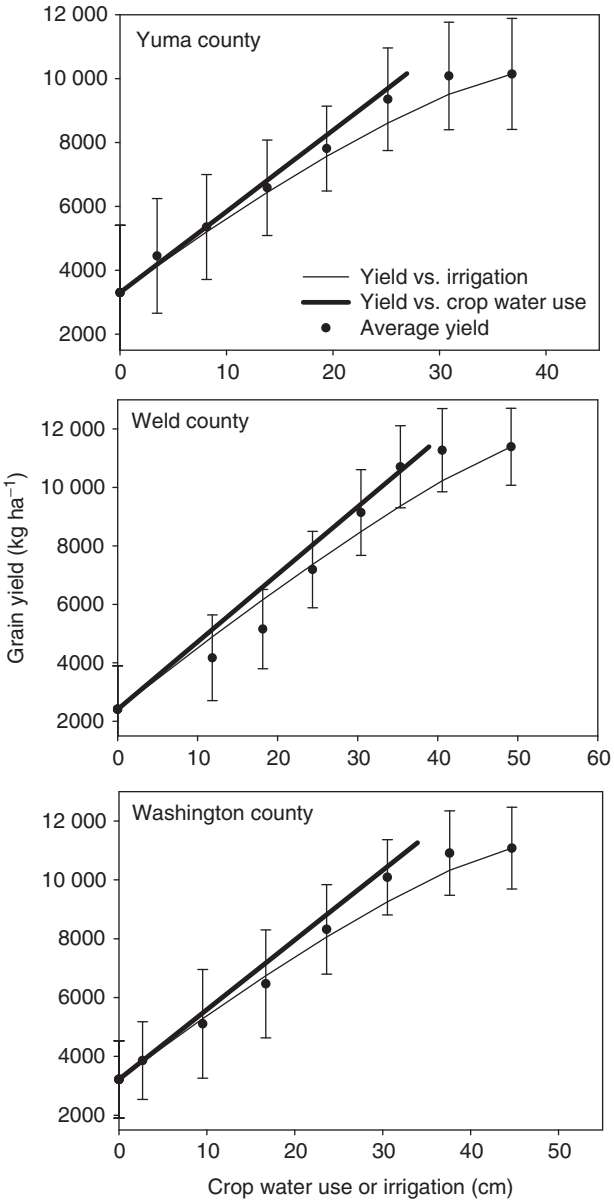

Figure 16 RZWQM with long-term weather data was used to generate these corn water production functions for three Colorado counties for use in the Colorado Water Optimizer to guide deficit irrigation and crops to irrigate. Reproduced with permission from Saseendran, S.A., Nielsen, D.C., Ahuja, L.R., Ma, L., Lyon, D.J., 2013. Simulated yield and profitability of five potential crops for intensifying the dryland wheat-fallow production system. Agricultural Water Management 116, 175–192.

Table 1 Regional Characteristics of DAYCENT simulations for the US

Major regions	*Minor regions*	*Crop simulated*	*Crop area simulated (Mha)*
Northeast	WI, MI, NY, VT, NH, ME, RI, CT, MA, NJ, and DE	Hay, corn, and soybean	7.2
Central	PA, WV, KY, TN, OH, IN, IL, IA, MO, and MN	Corn, soybean, and hay	47
Southeast	VA, MD, NC, SC, GA, FL, AL, MS, LA, and AR	Corn, soybean, hay, rice, and cotton	11
Southwest	OK, TX, NM, AZ, UT, NV, and CA	Corn, soybean, hay, rice, cotton, wheat, and sorghum	18.6
Northwest	KS, NE, SD, ND, CO, WY, MT, ID, OR, and WA	Corn, soybean, hay, wheat, and barley	39.4

Abbreviations: DAYCENT, DAY CENTURY.

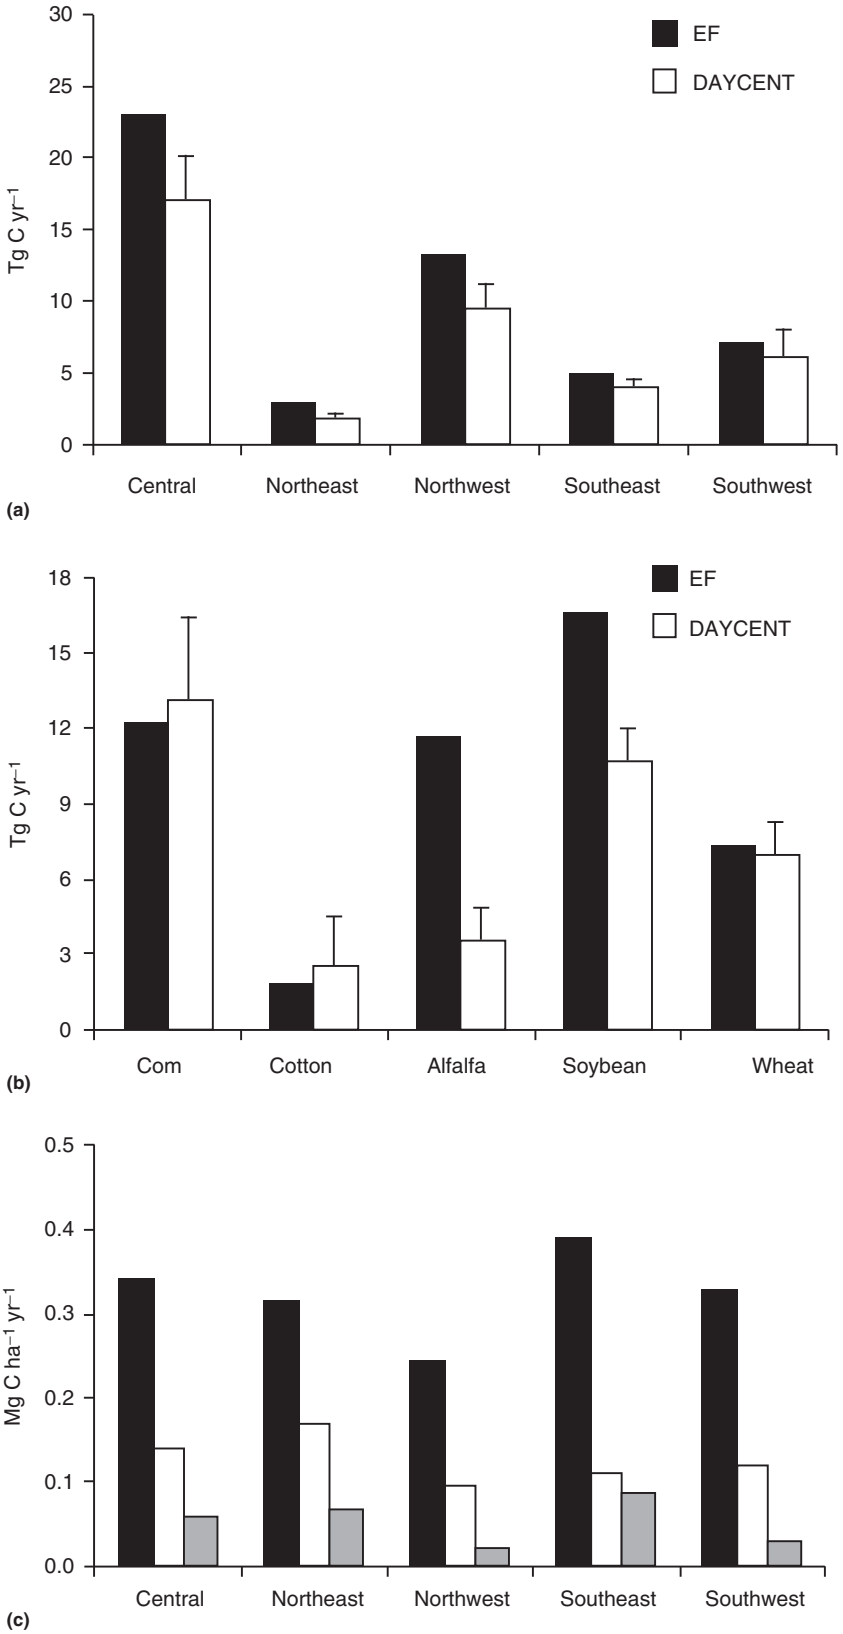

Figure 17 Simulated total N_2O with IPCC emission factor (EF) and DAYCENT model for (a) five regions in the United States, (b) five major crops in the United States, and (c) three management systems (from left to right, current management, pre-1940 management, and native vegetation). Results are 10-year mean and standard deviation in units of CO_2-C equivalents. Reproduced with permission from Del Grosso, S.J., Mosier, A.R., Parton, W.J., Ojima, D.S., 2005. DAYCENT model analysis of past and contemporary soil N_2O and net greenhouse gas flux for major crops in the USA. Soil And Tillage Research 83, 9–24.

during the 2070s, whereas under B1 emission scenario the maximum increase will be 13% during the 2060s. Comparatively, summer maize yield will gently decline by 15% and 12% under A2 and B1 emission scenarios, respectively. As ET is expected to increase by approximately 10% after the 2050s, a lower WUE (with relative changes of more than 25%) under both the scenarios were simulated for the 2090s. Climate-change effects on crop production also depend on soil water and soil N status. Daccache *et al.* (2011) simulated the potato crop under climate change for emissions scenarios A1FI and B1 for the 2050s, including CO_2 fertilization effects, with the SUBSTOR-Potato model included within the DSSAT. The yields showed only marginal increases of 3–6% due to the CO_2 effect because of limitations in nitrogen availability. In contrast, future potential yields, without restrictions in water or N, increased by 13–16%.

However, the predicted climate-change effects depend on the location, GCM scenarios used, and crop growth model. As there is large uncertainty associated with the GCM projected climate-change scenarios, it is very difficult to compare two climate-change studies in the literature. To overcome this uncertainty, the use of multimodel ensembles is better to project future climate. In a recent study of irrigated corn in the Great Plains of the USA, Islam *et al.* (2012) used an ensemble of 112 bias corrected and spatially disaggregated GCM projections at 1/8° spatial resolution for the period 1950–2099 and then ran the RZWQM2 model for the prediction of corn production in future climates. Simulation using the RZWQM2 model with the ensembles showed decreases in irrigated corn yield during 2020, 2050, and 2080 with changes in temperature. As shown in Figure 18, the changes in temperature (T) resulted in the same probability distribution curve as that of with changes in both temperature and precipitation (T + P; one overlapping the other in the figure.). Similarly, changes in precipitation (P) resulted in the probability distribution curves similar to that of the baseline (base) probability distribution curve. Thus, the changes in precipitation had no effect on yield because with full irrigation, 100% consumptive use demand was met by irrigation. When CO_2 fertilization effect (T + P + CO_2) was considered, there was less reduction in yield (Figure 18).

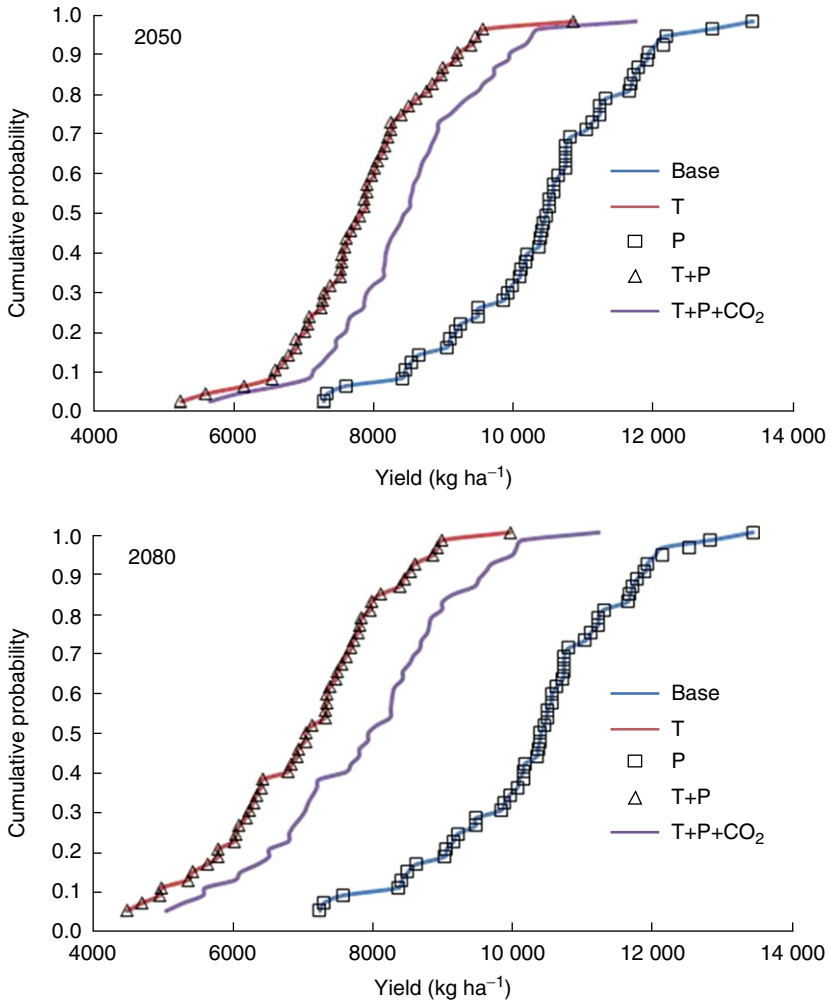

Figure 18 Cumulative distribution function (CDF) of corn yield in response to changes in temperature (T), precipitation (P), and CO_2 in future years over the baseline years for S1 (for an ensemble of 112 projections) scenario, at Greeley, CO, USA. Reproduced with permission from Islam, A., Ahuja, L.R., Garcia, L.A., *et al.*, 2012. Modeling the impacts of climate change on irrigated corn production in the Central Great Plains. Agricultural Water Management 110, 94–108.

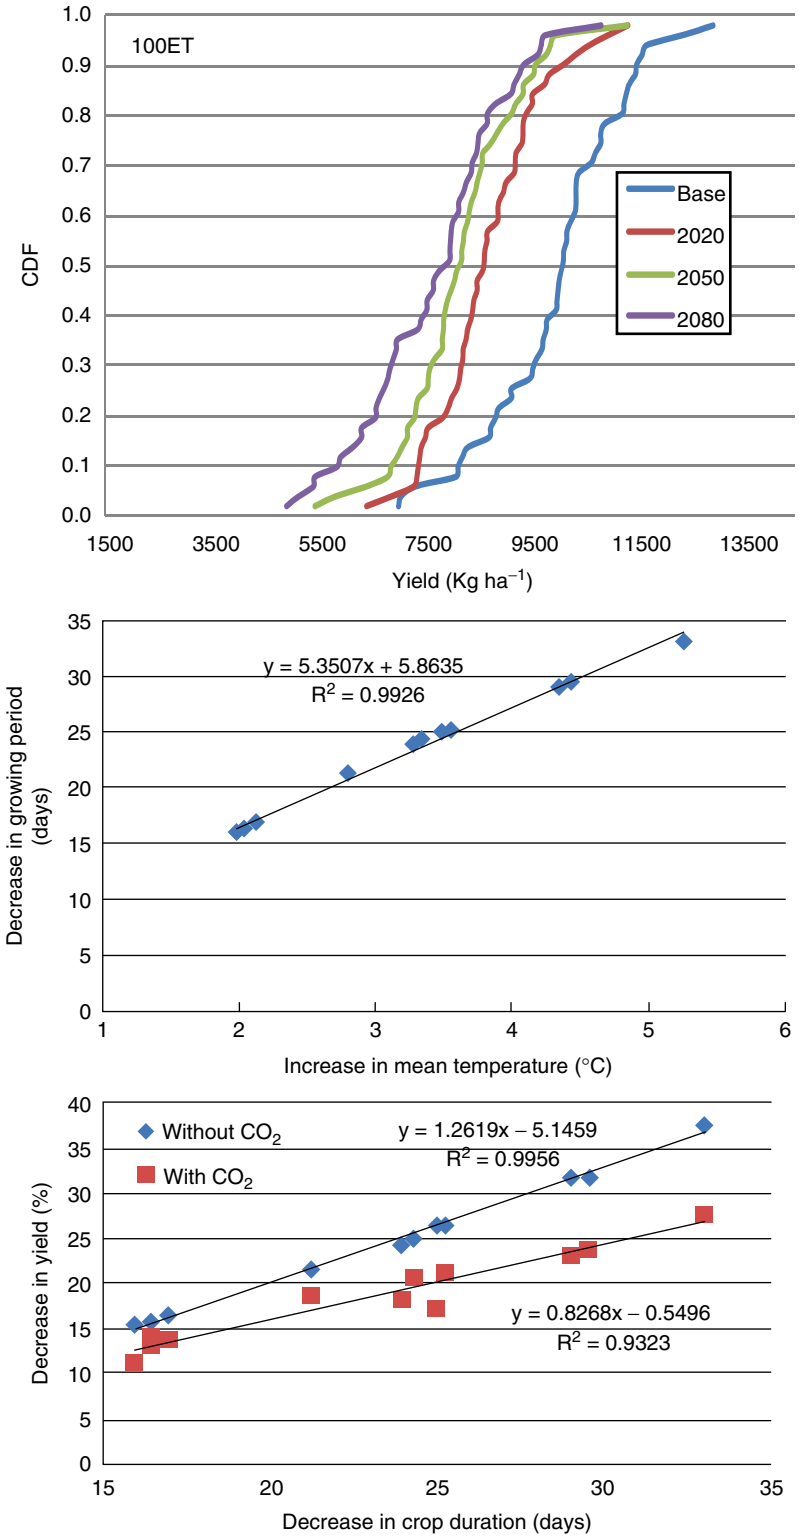

Figure 19 Effect of climate change on the cumulative distribution function (CDF) of fully irrigated corn yield (top); relationship between crop maturity duration with increase in temperature in all scenarios (middle); and relationship between mean decrease in crop yield with decrease in duration (bottom). Reproduced with permission from Islam, A., Ahuja, L.R., Garcia, L.A., *et al.*, 2012. Modeling the impacts of climate change on irrigated corn production in the Central Great Plains. Agricultural Water Management 110, 94–108.

Figure 19 shows climate-change effects on the probability distribution (cumulative distribution function (CDF), stemming from interannual variability) of fully irrigated corn production in CO, USA (Islam *et al.*, 2012). The yield decreased in future years. Additional simulation study also revealed that the relative decrease in corn yield due to climate change was smaller under deficit irrigation than under full irrigation. Simulated yield decreases were closely related to reduction in maturity duration of the crop, and the yield was inversely related to the number of days with maximum temperatures above the upper optimum for corn (32° C) (Figure 19). These results indicated that higher temperatures speed up crop maturity and may also directly decrease growth.

Exploring Adaptations to Climate Change

Models are also being used to study adaptations to climate change through cultivar changes and management practices. Using the APSIM model, Bassu *et al.* (2011) simulated a wheat variety with triticale traits and showed that some of the triticale traits increased wheat yield in the future climate-change scenarios. Gouache *et al.* (2012) studied impacts of heat stress during grain filling of wheat under climate change by coupling downscaled weather scenarios from the Action de Recherche Petite Echelle Grande Echelle climate model with a modified version of the ARCWHEAT phenology model. They also explored the effects of different agronomic solutions: earlier sowing, use of earlier cultivars, and improved genetic tolerance to heat stress. Adaptation through earlier sowing dates proved to be the least efficient. The use of earlier heading cultivars was somewhat efficient, and should be sufficient for the near future. Tolerance to heat stress appeared to be the most promising adaptation strategy.

Climate-Change Effects on Water Resources

Climate-change effects on water resources have gained more attention in the past decades with numerous publications in the literature using GCM-projected weather conditions. It is commonly agreed that climate change will result in more frequent droughts and extreme storm events (Green *et al.*, 2011). In a study at a large Eastern Mediterranean karst spring, Hartmann *et al.* (2012) combined different GCM models and five hydrological models to study climate-change effects on water availability and found that in the near future (2021–51) no conclusive results could be drawn. However, in the more distant remote future (2068–98), all the model combinations predicted a 15–30% decrease of water availability in the region of study. Wang *et al.* (2012) used the SWAT model coupled with climate models with high (A2) and lower greenhouse emission scenarios to study the monthly streamflow in Northwest China, and found that streamflow increased by 0.1–6.1% in the 2020s, 2050s, and 2080s. However, Khoi and Suetsugi (2012) simulated decrease in streamflow ranging from 3.1 to 16.7% in Vietnam. Coupling a spatial hydrometeorological model with GCM-derived climate-change scenarios, MacDonald *et al.* (2012) found that, although the average maximum snow water equivalent may not change under future climate conditions, the timing of spring snowmelt onset is likely to move up and leave a dry summer under future climate scenarios. The differences among various climate-change studies were due to differences in GCMs and emission scenarios, and due to the fact that climate-change effects are region specific (Bennett *et al.*, 2012).

Climate change is likely to result in hydrologic conditions and extremes that will be different from those for which the existing projects were designed. The potential climatic impacts may have significant ramifications for decision making regarding water allocation and management that are likely to be made in the coming decades. Tanaka *et al.* (2006) applied the integrated economic engineering optimization model California Value Integrated Network with two climate warming and a historical climate scenario for studying the impacts of climate and population change on the physical and economic performance of California's intertied water supply system. Simulation results showed that adaptation of California's water supply system would require large changes in the operation of California's large groundwater storage capacity, significant transfers of water among water users, and some adoption of new technologies. Payne *et al.* (2004) used variable infiltration capacity hydrological model and Columbia River Simulation Model along with Pacific Climate Model and RCM scenario to assess the potential effects of climate change on the hydrology and water resources of the Columbia River basin and to evaluate alternative reservoir operating policies designed to mitigate reservoir system performance losses. Simulation results showed that temperature changes dominated the simulated hydrologic effects by reducing winter snow accumulation, thus shifting summer streamflow to the winter. Combination of earlier reservoir refill with greater storage allocations for in-stream flow targets mitigated some of the negative impacts to flow, but only with significant losses in hydropower production.

Conclusions

Achieving environmental protection and food security are two somewhat conflicting goals in agriculture. With increasing demand on food due to escalating population, the society requires high yield from farmland, which calls for high N, water, and pesticide inputs. The latter will definitely increase the risk of environmental pollution. The key to this complex issue is to balance and optimize and assess risks, impacts, and tradeoffs. Agricultural system models have the unique capability to provide a balanced solution to this dilemma. This article has demonstrated some promising examples of model applications in the areas of water and N management, and climate-change effects on crop production. These applications can be extended to other environmental and food security issues, such as pesticides and phosphorus in runoff and soil erosion.

Glossary

Cumulative distribution function (CDF) Probability distribution with the possible value for the random value sorted from minimum to maximum.

Multivariate distribution A probability distribution with more than one random variable and they are related linearly (or nonlinearly) to each other so that their correlation is not zero.

Probability density function A schedule of probabilities associated with alternative values of a random variable, for example, a histogram or a bell-shaped curve.

Standard normal deviate (SND) A normally distributed random variable with mean zero and standard deviation of one.

Stochastic dominance A quantitative method for ranking risky alternatives.

Stochastic efficiency A quantitative method for ranking risky alternatives.

Stochastic variables Random variables.

Uniform standard deviate A random variable uniformly distributed between zero and one.

Univariate distribution A single random variable.

Introduction

Simulation has existed since man first started thinking through alternative ways for doing things. Thinking logically through solutions to problems is the most fundamental form of simulation. The modern computer greatly advanced simulation by allowing us to use machines to rapidly crunch through many different scenarios and provide summaries of the possible outcomes. Until the advent of the microcomputer, simulation models were relegated to universities and large corporations that had access to mainframe computers and programmers who developed simulation models using complex languages. With the introduction of Microsoft Excel spreadsheets, the simulation world has changed and anyone can now develop and utilize the power of simulation. Excel has become the language that businesses and researchers use to organize and process data. Simulation add-ins to Excel made the art of simulation more accessible to the business world, to students, and to researchers.

The purpose of this article is to introduce simulation as a tool for analyzing data and making probabilistic forecasts of variables that are not published or have risk about their forecasts. It is assumed that the reader is familiar with Microsoft Excel as this is fast becoming the language for developing simulation models and addressing risk in decision making.

Decision making in business and agriculture implies that management has a choice among alternative actions. The alternative actions could be different combinations of crops to produce, alternative production systems for crops or livestock, or different marketing or financial strategies for an agribusiness. If the decisions are to be made in a risk-free setting, the manager can easily determine which strategy is the best – the one with the greatest economic return. When decisions are made in a risky environment, the manager cannot use such a simple rule because the economic return for each alternative is a probability distribution of returns rather than a single value. One approach to decision making under risk is to simulate alternative strategies to estimate the distribution for each alternatives' return and then base the decision on these simulated distributions.

The purpose of simulation is to 'estimate the shapes of probability distributions for variables we cannot observe,' such as: profits, costs, or prices so the decision maker can make better decisions. The presence of risk complicates decision making and simulation is the best tool for analyzing the impacts of risk on key output variables (KOVs) of interest. Simulation produces hundreds of possible outcomes instead of a few discrete scenarios and the results show not only what could happen, but how likely each outcome is. Simulation makes creating graphs easier for different outcomes and the corresponding chances of occurrence.

In its most general form, simulation is simply the forecast of a KOV as a function of one or more exogenous variables or

$$\hat{Y} = a + b * X \qquad [1]$$

In this case Y is a function of X scaled by the parameter 'b' with the position on the number scale correction equal to parameter 'a,' and there is no risk. Because there is no risk, eqn [1] is a deterministic simulation model. A stochastic (or Monte Carlo) simulation model includes risk on one or more endogenous variables or risk added to the end of the equation as:

$$\tilde{Y} = a + b * X + \tilde{e} \qquad [2]$$

In eqn [2] the dependent variable is now a risky forecast with the addition of a probability distribution ($\tilde{e}$). The $\tilde{e}$ represents the risk for forecasting the $\hat{Y}$ and is based on the error term from econometrically estimating the equation to forecast the deterministic $\hat{Y}$. We can write eqn [2] in a more graphical sense by substituting a diagram of the probability distribution for risk in place of the $\tilde{e}$ or:

$$\tilde{Y} = a + b * X + \boxed{\text{⌒}} \qquad [3]$$

To simulate $\tilde{Y}$, a simulation software package randomly samples the probability distribution for $\tilde{e}$ many times (iterations)

 doi:10.1016/B978-0-444-52512-3.00127-3

and each time it adds the stochastic value for $\tilde{e}$ to the deterministic part of $\tilde{Y}$, which is $a+b*X$. After each iteration, the $\tilde{Y}$ value is recorded and after many hundreds of iterations the values for $\tilde{Y}$ provide an estimate of the shape of the empirical probability distribution for $\tilde{Y}$. By recalling, estimating the shape of the empirical distribution for $\tilde{Y}$ is the objective of simulation.

Most simulation models are much more complex than eqn [2]. The equations frequently have more than one exogenous variable, the exogenous variables themselves may be stochastic in addition to the stochastic error term, and there may be hundreds of equations necessary to define the system being modeled.

Steps to Build a Simulation Model

All simulation models have the following parts: (1) input data to define the system being simulated and the control variables, (2) historical data for the stochastic variables, (3) parameter estimation for the stochastic variables and simulated stochastic variables, (4) equations to calculate intermediate variables, and (5) equations to calculate the KOVs.

The pyramid in Figure 1 provides a paradigm for planning a simulation model. The analyst must start at the top of the pyramid by defining the KOVs to be calculated and provided to the decision maker. For an investment model the KOVs could include: net present value (NPV), present value of ending net worth (PVENW), annual net cash income (NCI), annual ending cash reserves (ECR), probability of economic success, probability of increasing real net worth, annual rate of return on investment (ROI), debt to asset ratio (D/A), etc. For a biological model the KOVs could be crop yield, rate of gain for livestock, or number of replacement heifers needed to maintain a herd size without purchasing cows 90% of the time. The simulation model will estimate the data necessary to calculate the empirical probability distributions (PDFs) for each of the KOVs and to calculate probabilities for the KOVs reaching targeted values.

Once the KOVs are known, the next step is to determine the reports that are needed to calculate the KOVs. For an investment model the reports are: an Income Statement, Cash Flow Statement, and a Balance Sheet. All of the KOVs can be taken from these reports or easily calculated from variables in the reports. The next step is to write the equations for all of the variables in the reports and the variables necessary to calculate variables in the reports. For example, the Income Statement has receipts for each enterprise. So the model must have an equation to calculate receipts for each enterprise as follows:

$$\text{Receipts for Enterprise}_{ij} = \text{Price}_{ij} * \text{Yield}_{ij} * \text{Acres}_{ij} \qquad [4]$$

where i represents year and j represents the enterprise (crops or livestock).

In the process of writing the equations to calculate all of the variables in the model, the analyst should identify exogenous variables, management control variables, and stochastic variables. In eqn [4], Acres_{ij} is a control variable if the model is to investigate the profitability for alternative crop mixes. Other control variables that affect the profitability of a business are: terms for initial and new debts, initial and projected asset values, available resources (machinery complement, acres owned and leased, etc.), enterprises for the business (crops grown, livestock raised), input requirements and costs for enterprises (e.g., quantity of fertilizer, seed, herbicides, labor, fuel, or for a livestock model the inputs are hay, protein, and supplements fed per head of livestock). The list of exogenous variables will depend on the system being modeled and the degree of detail for the model.

Stochastic variables are identified in the process of writing the equations for the model. Stochastic variables are the variables the decision maker cannot forecast with accuracy or are control variables. In eqn [4], the prices and yields for the crop are obviously stochastic as the decision maker cannot control prices and yields as these variables are determined by markets and weather. A detailed model may include prices for outputs (e.g., individual crops and livestock) and each input (e.g., seed, fertilizer, chemicals, labor, utilities, livestock feed ingredients, etc.) as stochastic variables. In addition to these types of stochastic variables, the error terms for all econometric equations (such as $\tilde{e}$ in eqn [2]) should be included as a stochastic variable. During this step of model building, the analyst should assemble the historical data for the stochastic variables and the variables to be forecasted using econometric equations.

The steps to build the simulation model in Figure 2 are essentially a reversal of the steps in Figure 1; this time we start at the bottom of the pyramid. The first step is to estimate the parameters to define the PDFs for the stochastic variables. Depending on the simulation software available this can be an easy or a complex task. Parameter estimation for stochastic variables is very important to simulation modeling and is covered in-depth in the next section.

Once the parameters to simulate the stochastic variables are developed, the next step is to simulate the random variables and validate that they indeed reproduce the historical PDFs for the random variables. This step is often ignored by simulation modelers but it is crucial to prove the usefulness of the completed model. Validation tests for testing the stochastic variables start with the Student-t test to ensure that the simulated means statistically equals their historical (or intended) means. The second test is an F test which is used for testing if the

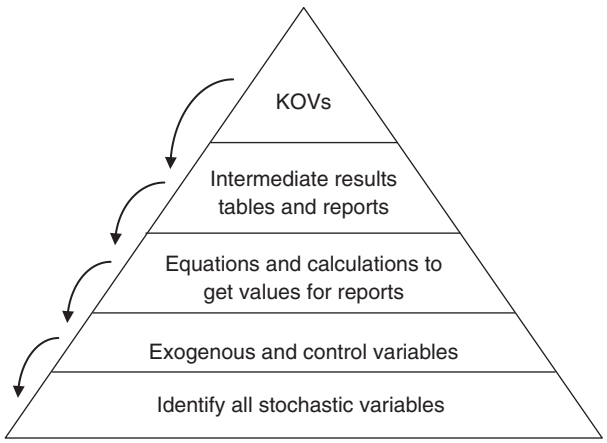

Figure 1 Steps for designing a simulation model. KOVs, key output variables.

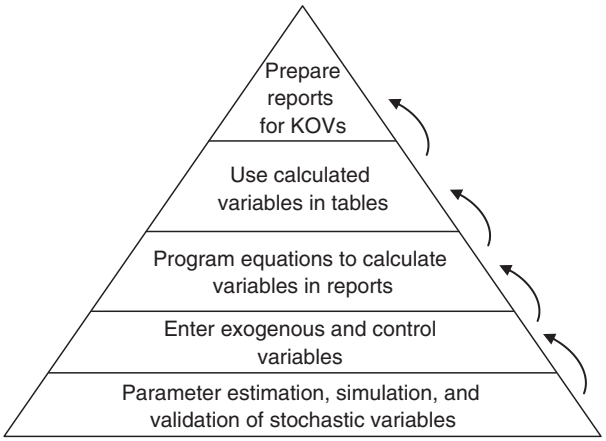

Figure 2 Steps for building a simulation model.

variance for the simulated variable statistically equals the variance historical variability over a period used to estimate parameters for the distribution. If the stochastic variables are correlated then the Box's M Test should be used to test the covariance of the simulated variables against the historical covariance and the Hoteling's T test should be used to test the historical mean vector of the stochastic variables against their simulated mean vector. A complete homogeneity test can be used to simultaneously test the mean vectors and the covariance matrices. After validating the simulated random values for the stochastic variables they can be used in the model. Without detailed validation one is just perpetuating the old argument against simulation: garbage in and garbage out (GIGO).

The stochastic variables are used with the exogenous variables and control variables to program the equations in the model to calculate the intermediate variables. Econometric equations that use stochastic error terms are programmed at this point in the model; however, most of the equations in a simulation model are identities and are easily programmed. It is recommended that the individual equations be kept simple so they can be easily verified rather than programming long equations with many parts and conditions. An Excel worksheet has more number of cells for equations than you will ever need and so there is no need to minimize the number of cells used. Use one cell for each equation and program the equations in a logical order so that the calculations flow from one step to the next down the Excel worksheet. For example, the logical flow of equations for a farm investment model is to use five equations to calculate production, variable costs of production, total production costs, receipts, and profit in the following order:

$$Production_i = \text{Acres}_i * Yield_i \quad [5]$$

$$Variable\ Costs_i = \text{Variable Costs per Unit}_i * Production_i \quad [6]$$

$$Total\ Costs_i = Variable\ Costs_i + \text{Fixed Costs}_i \text{ per Acre} * \text{Acres}_i \quad [7]$$

$$Receipts_i = Price_i * Production_i \quad [8]$$

$$Profit_i = Receipts_i - Total\ Costs_i \quad [9]$$

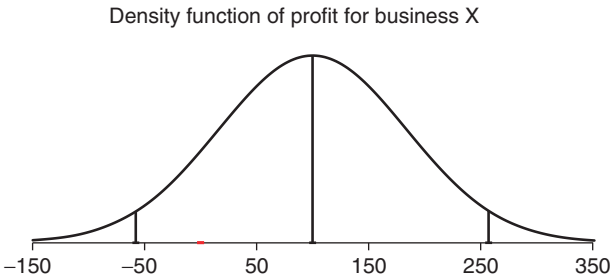

Figure 3 Probability density function for a KOV of profit.

where all variables in italics become stochastic variables because they are functions of the random variables that are in bold.

The stochastic variables for the model are prices and yields but by including them in eqns [5] and [8] it makes all of the other variables stochastic as well. It is through this process that the simulation model is able to forecast the probability distribution for profit. Note that the exogenous variables in the model are acres, variable costs per unit, and fixed costs. The exogenous variables are control variables set by the analyst and can be used for testing alternative scenarios.

The next step in model building is to assemble the calculated variables into reports and tables that are useful for summarizing the model's results. The receipts and expenses for a business model logically are summarized in an income statement which is followed by a cash flow statement and a balance sheet. An example of these summary tables is provided in the Appendix.

The final step in programming a simulation model is to develop reports using the KOVs. Reports can include tables with the summary statistics (means, standard deviation, coefficient of variation, minimum, and maximum) for all of the KOVs, and charts of the KOVs. Probability density charts are very useful as they show that the KOVs are stochastic (Figure 3). Cumulative distribution charts are frequently more useful as we can read the probabilities of alternative outcomes directly from the chart, for example, the probability that the KOV is less than zero is 10% (Figure 4). The two figures depict the results for the same output variable but the CDF is easier to interpret.

Model verification of the completed simulation model must be undertaken as soon as the model is completed. Verification is the process used to test that every equation in the model is functioning as intended. This means that testing each equation to ensure that its independent variables come from the appropriate cells in the worksheet, i.e., that crop production is actually calculated using the cells that have acres and yields for the correct crop and that the model does not multiply sorghum yield and wheat acres. Each equation must be checked to ensure that the variables are using the correct time period (months, years, etc.) and that the equations are not using crossing periods, i.e., yields in 2013 are used to calculate production in 2013. After verifying all equations it is recommended that a series of verification tests be used to further verify the model's ability to forecast the system being analyzed.

Figure 4 Cumulative distribution function (CDF) for a KOV of profit.

Simulating the model using historical data as the starting point and comparing the forecasts to history is a place to start in the verification process. It is recommended that the analyst compare the model results to historical records of the KOVs and published results for other models. This may be difficult if the model is analyzing investments in proposed businesses or business plans that have not been tried. In these cases a Touring Test is appropriate. A Touring Test for a model involves defining a standard scenario, running the model, recording the outcomes, and having experts review the inputs and the outputs. Reviews by experts will help identify inconsistencies in the model's results. For example, a misplaced sign on a coefficient can make demand upward sloping or supply downward sloping, both of which can be detected in a Touring Test.

Parameter Estimation for Stochastic Variables

The random variables are what make the simulation model a stochastic model. To simulate the random variables one must know what distributions they come from, their variability, and their position on the number scale. The parameters for a stochastic variable define the variability and position on the number scale from plus and minus infinity. Parameters to define random variables are estimated from their historical data. A basic understanding of random numbers and probability distribution is necessary to estimate the parameters for stochastic variables.

We start with the simplest of random variables, the uniform distribution as it is used to simulate all random variables. The most general form of the uniform distribution is the Uniform Standard Distribution (USD) which is written as USD~$U(0,1)$. The parameters for the USD are a minimum of zero and a maximum of one. A value drawn at random from a USD can be used to simulate any distribution through the inverse transform method. For example, if $\tilde{Y}$ is a uniform random number distributed over the range of 10–20 (i.e., $\tilde{Y}$~$U(10,20)$) we simulate $\tilde{Y}$ as follows:

$$\text{USD} = \text{UNIFORM}(0,1) \text{ or } \text{RAND}(0,1)$$

$$\text{depending on the simulation add-in} \qquad [10]$$

$$\tilde{Y} = \text{minimum} + (\text{maximum} - \text{minimum}) * \text{USD} \text{ or}$$

$$\tilde{Y} = 10 + (20 - 10) * \text{USD} \qquad [11]$$

Because the USD is always between zero and one, $\tilde{Y}$ has to lie between 10 and 20 on the number line and there is an equal probability that $\tilde{Y}$ will be in the interval of 12 and 14 or 16 and 18. The uniform distribution itself is not used to simulate a random variable unless the shape of the distribution is completely unknown and we only know the minimum and maximum.

The most popular distribution for simulating random variables is the normal distribution because it is easy to estimate the parameters. For that reason many modelers take the easy route and just assume the random variables are distributed normal. Before making this assumption, tests for normality should be applied to the random variables. The parameters for the normal distribution are its mean and standard deviation and we denote that a random variable $\tilde{Y}$ is distributed normal as: $\tilde{Y}$~N(mean, standard deviation). A normal distribution can be simulated with the following equation:

$$\tilde{Y} = \text{Mean} + \text{Standard Deviation} * \text{SND} \qquad [12]$$

where SND = NORMSINV(USD) and USD is defined in eqn [10]. In this equation SND is the standard normal deviate which has a normal distribution with a mean of zero and a standard deviation of one. NORMSINV is an Excel function to convert a USD into a standard normal deviate.

The normal distribution's parameters, mean and standard deviation, can be calculated with any statistical software or calculated directly in Excel.

To estimate parameters for a normally distributed random variable, all that is needed is the historical data for the random variable. To use the historical data to define a random variable, one must first remove the systematic risk before estimating the parameters for the probability distribution. With agricultural data, and particularly with yields and prices, there is frequently a trend or seasonality and cycles which must be removed before attempting to estimate parameters for a random variable. The trend can easily be removed by fitting an ordinary least squares (OLS) regression to the historical data and letting the

unexplained residuals from the regression be the risk to be simulated as the stochastic component to $\tilde{Y}$. In eqn [13] a trend regression is fit to the historical variable and the stochastic residuals are calculated in eqn [14]:

$$\hat{Y} = a + b * T \quad [13]$$

where T is a variable that increments by 1 as 1, 2, 3, … or 2000, 2001, 2002,

$$\tilde{e} = Y - \hat{Y} \quad [14]$$

The $a+b*T$ part of eqn [13] is the deterministic component in eqn [2] and $\tilde{e}$ is the stochastic component of eqn [2] that no longer has a systematic trend. Another way to say this is that $\tilde{e}$ represents the risk about the trend or the OLS forecast and in simulation it represents the risk about the forecasted mean or $\hat{Y}$. If the random variable $\tilde{Y}$ has a structural relationship to other variables, then a more complete OLS equation that includes all of the independent variables must be used to calculate the $\tilde{e}$ series. The residuals should be tested for normality and if they are normally distributed then $\tilde{Y}$ can be simulated as a normally distributed random variable using eqn [15]:

$$\tilde{Y} = \hat{Y} + (\text{Standard Deviation for } \tilde{e} * \text{SND}) \quad [15]$$

A caution in using the normal distribution is that if the mean or $\hat{Y}$ assumed for the simulation in eqn [12] or [15] is greater than the historical data, the simulated variables will have less relative risk than the historical data and *vice versa* if the mean or $\hat{Y}$ is less than the historical mean.

Many other parametric distributions can be used to simulate random variables in stochastic models. The most frequently used parametric distributions are beta, gamma, log normal, Weibull, and exponential. Estimating parameters for these distributions is more complicated and requires special software such as those found in Simetar© and Best Fit©. Whatever parametric distribution is used, you must first remove the systematic variability to identify the actual risk in the stochastic variable before estimating the parameters for the appropriate (or assumed) distribution.

When insufficient data are available to estimate the parameters for a parametric distribution, one can use a nonparametric distribution. The triangle distribution is used frequently because it is easily parameterized with only three values: minimum, mean, and maximum. The triangle distribution has a significant problem in that it never returns the exact minimum or maximum. If one solicits the extreme values by asking for a minimum or maximum that one might expect 1 year in 10 (or 10% of the time), then the triangle will greatly underestimate the frequency of the tails for the distribution. Understating the risk in the tails is extremely problematic as the outcomes in the tails are critical to providing an accurate estimate of the risk associated with a decision.

The empirical distribution is a nonparametric distribution that is similar to simulating a histogram of the random variable with interpolation between the points. The empirical has a finite minimum and maximum and it exactly matches the shape of the distribution as observed in the historical data. The best way to simulate an empirical distribution is to convert the residuals from trend (or structural OLS model, or mean) into fractional deviates and simulate these deviates as an empirical distribution or as

$$S_i = \text{Sorted}(\tilde{e}_i / \hat{Y}_i) \quad [16]$$

$$\tilde{Y} = \hat{Y}_i * (1 + \text{EMP}(S, F(x), \text{USD})) \quad [17]$$

The $F(x)$ term represents the cumulative probabilities for the sorted deviates about the trend or mean forecasts. During simulation the USD is used in the inverse transform formula to simulate a random deviate which is added to one and multiplied by the forecasted Y value. If $\hat{Y}$ is equal to the historical mean, the resulting random values are distributed identical to the historical data without bias from assuming a probability distribution for the random variable. Even if $\hat{Y}$ is different from the historical mean, the simulated values will have the same coefficient of variation as the historical data so that relative risk is maintained as the mean increases or decreases over time.

When a stochastic model has more than one random variable, one must consider the possibility that the random variables are correlated or that causality may exist between or among the variables. When two random variables are positively correlated and the correlation is ignored, the mean for the product of these random variables ($\tilde{Y}_3 = \tilde{Y}_1 * \tilde{Y}_2$) will be biased and its variance will be understated. The variance is overstated if the two random variables are negatively correlated. So if correlation between and among the random variables is present, one must account for it and use a multivariate probability distribution rather than individual distributions for each random variable.

Multivariate normal distributions have been used in simulation models for many years. Clements *et al.* (1971) first demonstrated its use in an agricultural simulation model. Multivariate non-normal (MVNN) distribution was introduced by Richardson and Condra (1981) and their approach was expanded on by Richardson *et al.* (2000). The MVNN approach is described here as it includes the multivariate normal as a special case. The parameters for a MVNN distribution are the correlation matrix of the residuals plus the parameters for the individual random variables' distributions (normal, beta, gamma, empirical, etc.). A vector of J correlated uniform standard deviates (CUSDs) is simulated using the square root of the correlation matrix and a vector of independent standard normal deviates (ISNDs) to simulate a MVNN distribution with J variables:

$$\text{CUSD}_{[J\text{x}1]} = \text{NORMSDIST}(\sqrt{(P_{[J\text{x}J]}} * \text{ISDN}_{[J\text{x}1]}) \quad [18]$$

where $\sqrt{(P_{[J\text{x}J]})}$ is the square root of the correlation matrix and NORMSDIST is the error function in EXCEL to convert SNDs into USDs.

The CUSDs are used in the inverse transform equation to simulate each of the J random variables, as in eqn [18]. Simulation add-ins for Excel, such as Simetar©, include functions that simulate the CUSD vector in one step so that including correlation for multivariate distributions is quite simple. Validation of random variables simulated using a multivariate distribution requires the use of the multivariate validation tests described in the Section Steps to Build a Simulation Model.

Recent research in the area of simulation has promoted the use of copulas to incorporate causal relationships between and among random variables. The procedure described in eqn [18] is a normal copula. The Clayton and Frank copulas can be simulated in Simetar© using eqn [18] by replacing the correlation matrix ($P_{[IxJ]}$) with a Kendall's Tau concordance matrix. Validation of a multivariate distribution simulated using a copula is more difficult and is not covered here.

Applying Simulation Models

Simulating a single scenario is useful, but what simulation models were meant to do was to simulate multiple scenarios so that decision makers can compare the outcomes for making better choices. Multiple scenarios can easily be defined using alternative values for the decision maker's base values of the control variables. Each scenario in a simulation is unique because it is based on a different set of assumptions for the exogenous variables.

Examples of decision problems that are suitable for simulation as scenarios are: comparing insurance options for yields, revenue, weather, etc.; farm program participation options; crop mixes and enterprise selection, such as adding or dropping a livestock enterprise on a farm, machinery replacement by purchasing or leasing; increasing or decreasing acreage to a farm; marketing strategies, such as contracting, selling at different times of the year, hedging, or options; and portfolio analysis using stocks and bonds.

The different simulation add-ins for Excel allow for scenario analysis in different ways. Be sure the add-in you use forces the random variables to use exactly the same USDs for the random variables across all scenarios. This will cause the scenarios to all face the same risk and ensure that the KOV results are only different because of the values of the control variables assumed for the scenarios. Otherwise, differences in the KOVs are due to different risks and the different values assumed for the scenario variables, and the results are not useful.

After simulating multiple scenarios the analyst must help the decision maker decide which is the best scenario. This is the area of ranking risky scenarios and is covered in the next section.

Ranking Risky Alternatives

The results from simulating multiple scenarios are multiple empirical distributions for each KOV. Usually the decision maker will focus on one KOV for ranking risky alternatives. For annual models the KOV of choice is likely to be NCI, ECR, or production. For a multiple-year planning horizon model, the KOV should be one that converts the stream of annual returns into present dollars such as NPV as indicated in eqn [19]:

$$\begin{aligned}\text{NPV} = &-\text{Beginning Net Worth}\\ &+\sum(\text{Cash Withdrawals}_i)/(1+r)^i\\ &+\text{Ending Net Worth}/(1+r)^I \qquad [19]\end{aligned}$$

where r is the discount rate and i represents the years simulated $i = 1, 2, 3, \ldots, I$.

To rank the multiple KOVs developed by the simulation model, we can rely on several techniques, such as: means, mean variance, stochastic dominance, stochastic efficiency, and StopLight charts with target probabilities. For a complete comparison of these and other risk ranking strategies see Richardson and Outlaw (2008). Ranking risky alternatives based on the simulated means is only useful if the decision maker is risk neutral, which is likely not the case.

Mean variance ranking is easy to use and helps identify the scenario with the greatest mean return and the least variance, but can lead to indifferences between scenarios that are not resolvable. See Robison and Berry (1980) for a more complete description of mean variance analysis.

Stochastic dominance is a very useful method for ranking risky alternatives. Three types of stochastic dominance techniques are well defined for ranking risky alternatives: first degree, second degree, and generalized stochastic dominance. First-degree stochastic dominance can be used to rank risky alternatives when the empirical CDFs for the alternatives do not cross. A rational decision maker will prefer the alternative associate with the scenario furthest to the right in **Figure 5**. The right-most scenario (NPV 2) is preferred over the fourth scenario (NPV-4) because it offers the most income for the least risk at each point along the CDF. However, first-degree stochastic dominance cannot rank the other scenarios as their CDFs cross.

Second-degree stochastic dominance measures the differences between the CDFs and arrives at a ranking based on the sum of the area that is greater for the distribution that is further to the right. In the case of **Figure 5**, second-degree stochastic dominance ranks scenario 1 over 2 and 4, and it ranks scenario 3 over 2 and 4, but is unable to rank scenario 1 versus 3. Generalized stochastic dominance ranking of the four scenarios considers the decision maker's utility function and degree of absolute risk aversion and ranks scenario 3 as the most preferred. A disadvantage of using generalized stochastic dominance is that the procedure requires that one knows the decision maker's absolute risk-aversion coefficient. See Meyer (1977) for a mathematical description of generalized stochastic dominance.

Another risk ranking procedure, which uses the decision maker's utility function, is stochastic efficiency but it does not require the decision maker's risk-aversion coefficient. Stochastic efficiency assumes a utility function and ranks the risky alternative over a range of possible risk-aversion levels which are set wide enough to include the relative risk aversion for the decision maker. The results of ranking the risky alternatives depicted in **Figure 5** are presented in **Figure 6** using stochastic efficiency. Stochastic efficiency assumes decision makers prefer more to less and calculates the certainty equivalence (CE) for each risky alternative at many different levels of risk aversion ranging from risk neutral to extremely risk averse. The decision maker chooses the risky alternative that has the highest CE at their relative risk-aversion level. For the risky alternatives in **Figure 6**, all decision makers who are risk averse choose scenario 3. The risk-aversion coefficients in **Figure 6** are: 0, neutral; 1.0, normal; 2.0, moderate; 3.0, somewhat; and 4.0, extremely risk averse, based on the nomenclature proposed by Anderson and Dillon (1992). For a more complete description of stochastic efficiency see Hardaker *et al.* (2004).

The easiest risk ranking methodology, which takes into consideration the complete empirical distributions for the

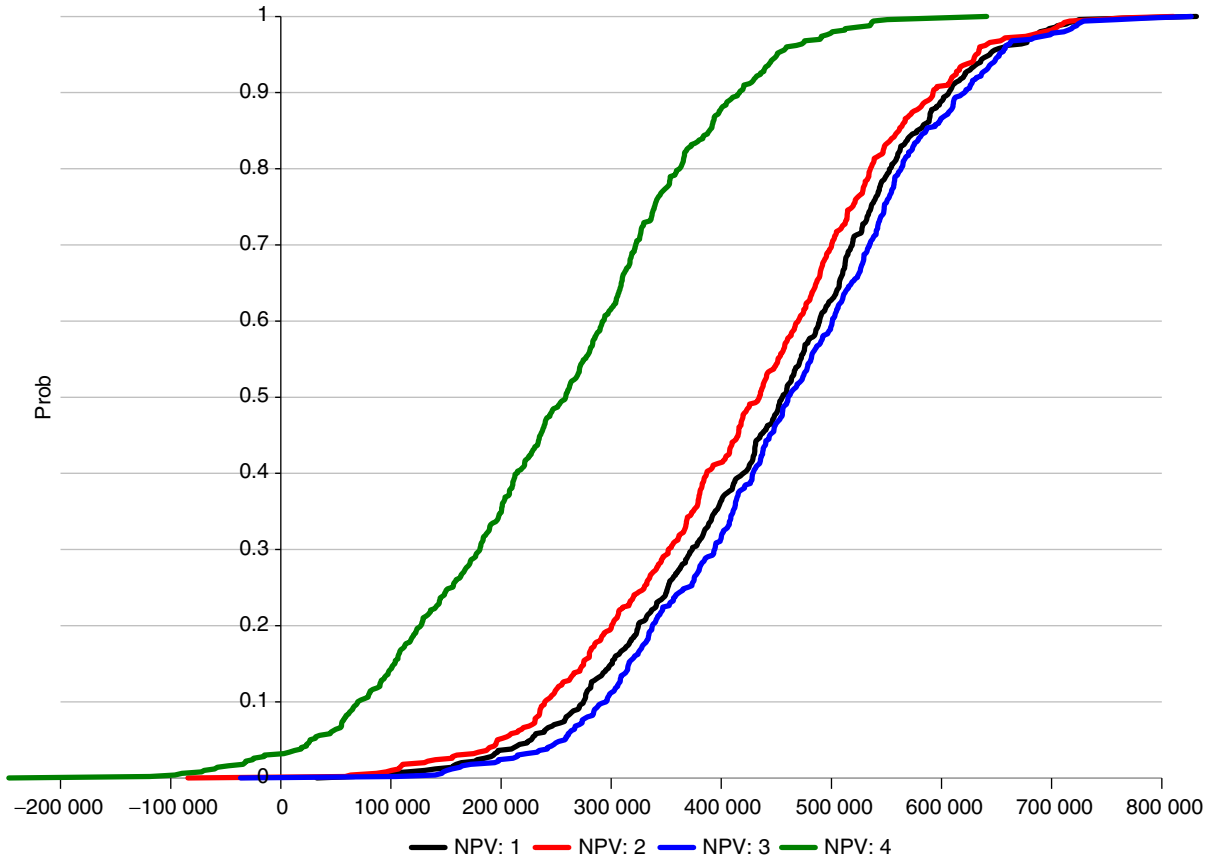

Figure 5 CDFs of NPV for four scenarios. NPV, net present value.

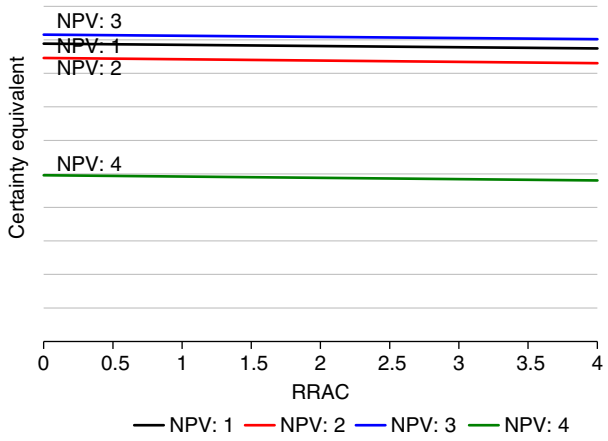

Figure 6 Ranking risky alternatives using stochastic efficiency.

KOV, is the StopLight chart for the probabilities of achieving target values for the KOV. The decision maker provides target values for the KOV and the chart presents the probabilities for exceeding the upper target in green and the probabilities for being less than the lower target in red. Green is good and red is bad is the criteria for ranking the risky alternatives. Based on the chart it is easy to see why risky alternative 3 was selected by stochastic efficiency and generalized stochastic dominance. This method of ranking is very easy to explain to decision makers, particularly if they are not trained in economics or statistics (Figure 7).

The risk ranking methods presented here require complex mathematical calculations that are beyond the capabilities of most simulation packages. See the references cited for more details on the mathematical presentations of the methods.

Selection of a Simulation Add-In for Excel

Excel is an excellent vehicle for a simulation model and a simulation add-in is the motor that makes the model run. Excel provides the basic formulas for programming a stochastic simulation model, i.e., addition, subtraction, multiplication, division, and fundamental statistical tools for calculating means, standard deviation, and sums. Excel also includes a powerful set of graphics capabilities that allows users to develop graphs that are useful for presenting the results for stochastic simulation models. Excel has many other useful statistical functions that can be used by more advanced simulation modelers, but they are not designed for researchers who are just starting in the field of stochastic simulation.

As with many things in life, when starting on a new trek it is good to seek the best advice and help possible. In the case of simulation this means using an Excel add-in that is designed to support development of stochastic simulation models. The leading simulation add-ins are: Simetar©, @Risk©, and Crystal

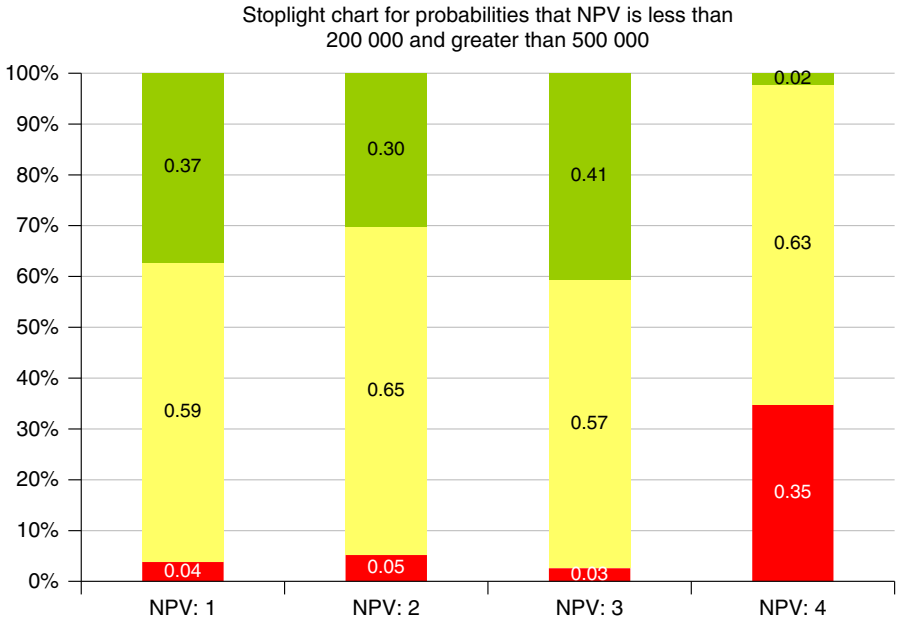

Figure 7 StopLight chart for ranking risky alternatives.

Ball©. All three have been on the market for some time and have their faults and positive features. More information on the three add-ins is available on their web sites.

In selecting a simulation add-in for Excel, the author recommends to seek out a package that meets your needs and is easy (preferable intuitive) to use based on your mode of working. The following is a checklist of features to look for in selecting a simulation add-in for Excel:

- Pseudorandom number generator: user-defined seed to start the random number generator at the same place each time so that every time a model is run it can return the same stochastic results.
- A nondegenerative random number generator: test the random number generator by simulating 100 000 or more USDs to make sure that the last 1000 are indeed distributed $U(0,1)$.
- Random numbers simulated with a Latin hypercube procedure: the alternative sampling procedure is a Monte Carlo procedure, which tends to under- and oversample the USD and thus force one to simulate an obscenely large number of iterations to achieve stable stochastic distributions. Owing to a more efficient sampling procedure the Latin hypercube can generate stable stochastic distributions with less than 2000 iterations instead of tens of thousands with a Monte Carlo procedure.
- Large number of available probability distributions: analysts need not be limited to a small number of probability distributions from which to simulate random variables. The more distributions included in the software, the better.
- Multivariate distribution capabilities: for reasons described above, the add-in must have the capability to simulate correlated USDs so that the model can simulate multivariate distributions without variance bias.
- Copulas to simulate concordance between random variables: when random variables are related in a nonlinear fashion, the model must have the capability to simulate their concordance.
- Regression and forecasting options included in the package: it is more accurate and efficient to estimate OLS coefficients and residuals in the simulation packages than to do it in a second Excel add-in. In addition, forecasting packages such as times series, exponential smoothing, seasonal indices, and moving averages are frequently needed in simulation to estimate the residuals about the forecast for a stochastic variable and to forecast means for the random variables.
- Parameter estimation capabilities for parametric and nonparametric distributions: parameter estimation for other than the uniform and normal distributions requires the use of method of moments or maximum likelihood estimators. These parameter estimation procedures are beyond the capabilities of most simulation modelers so they need to be included in the simulation add-in.
- Statistical tests for validating simulated variables: until the random variables generated by a simulation model are validated, the model should not be used for decision making. Student-t and F or Chi-square tests as well as multivariate validation tests must be included in the add-in for ease of validating the stochastic variables.
- Risk ranking tools: stochastic dominance, stochastic efficiency, and StopLight charts are essential features in a simulation add-in if the modeler wants to help the decision maker select the best scenario.
- Graphing capabilities that complement Excel: specialized charts such as PDFs, CDFs, and Fan Graphs are helpful to display the shapes of the simulated KOVs and for testing the model.

- Ease of specifying and running multiple scenarios: simulation is about comparing risky alternatives so the add-in must provide a transparent and easy-to-use method for simulating multiple scenarios with exactly the same risk from one scenario to the next.
- Simulated values are summarized in a separate worksheet updated after each simulation: this feature allows Excel to automatically update summary tables and risk ranking charts developed by the user after each simulation.

Getting Started with Stochastic Simulation

The way to get started building and using stochastic simulation models is to start with a small model that has two random variables and two or three control variables. Such a model is described in eqns [5]–[9]. Obtain a 10–20-year series of prices and yields for a crop and assume these random variables are independent. Use accepted budgets for the marginal costs to harvest and haul the production and assume all other production costs are fixed costs per acre. Simulate the model for 1 year and plot the probability distribution for profit. Next, change the control variables and re-simulate the model. Next, make acre and fixed costs control variables for a five scenario analysis. Graph the CDFs of profit for the five scenarios to determine the effects of changing these variables.

After becoming comfortable with simulating the model for 1 year, expand it to simulate for 5 or 10 years. First, this involves forecasting mean yields and prices for each year in the planning horizon. Next, it requires a separate random value for each year. The new random variables all have to be validated to ensure that the simulated means for each year equal their assumed means. Because the model is now a multiple-year model, include an income statement, a cash flow, and a balance sheet so the NPV can be calculated as the KOV. Expand the KOVs to include annual NCI, annual ending cash (EC), and the probability that these variables will be positive each year. Next, run five scenarios using alternative acres, fixed costs, and mean yields. Rank the five risky scenarios.

To the final model, change the stochastic procedure to simulate the annual prices and yields as a multivariate empirical probability distribution. Compare the simulated annual NCIs for the model with independent random variables to the model with correlated random variables. Rank the five scenarios to see if the rankings change. Have fun.

Examples of Applying Simulation to Agriculture

Four examples of applying simulation to problems in agriculture are presented in this section. The first example is a summary of a policy analysis conducted by the Agricultural and Food Policy Center (AFPC) at Texas A&M University in 2012 at the request of the US Congress, House Agriculture Committee. The second example is the results of an investment analysis to demonstrate the use of simulation for analyzing a business before investing. The third example is a simple study to demonstrate how simulation can be used to analyze alternative insurance options for a farmer. The last example is a summary of an analysis of alternative technologies and how they could potentially improve the economic and nutritional sustainability of small holder farmers in a developing country.

Each example is presented using the following format: describe the problem to be analyzed, describe the model used and the stochastic variables, summarize the results, and present the charts and tables used to present the results to the decision makers. The full reports for the first three examples are available on request from the author. The fourth example has not been published; however, the simulation model will be made available for free from the author.

Farm Policy Analysis

In 2012, the House and Senate Agriculture Committees in the US Congress were busy formulating a new farm bill. Both Committees had formulated a bill and the AFPC was asked to conduct a risk-based analysis of the two farm bills (Outlaw *et al.*, 2012). The full report is available on the AFPC website at http://www.afpc.tamu.edu/pubs/0/578/wp%202012-03%20-%20to%20post%20to%20web.pdf. The two farm bills were very complex with several options in each bill. The AFPC was requested to conduct a farm-level economic analysis using the Farm Level Income and Policy Simulation Model (FLIPSIM) developed by Richardson and Nixon (1986).

FLIPSIM is a Monte Carlo simulation model for simulating the economic impacts of alternative farm programs and income tax policies on the economic viability of representative crop, dairy, and beef cattle farms (Richardson and Nixon, 1986). The model was initially completed in 1980 and has been expanded and enhanced continuously since then. The model has been used to advise the US Congress on every farm bill since 1983 and is widely cited, based on the more than 14 900 hits on a Google search of 'FLIPSIM-model.' The model can be summarized simply as a multiyear simulation of a farm business with stochastic production and product prices. The model includes farm policy formulas and income tax regulations so that it is able to simulate a farm under alternative policy scenarios. For the example summarized here, the policy options considered by the US Congress were added to the model and 65 representative crop farms were simulated for 5 years.

Scenarios Analyzed

Both the US Congress, Senate and House Farm Bills discussed previously were analyzed using the representative farms for the following scenarios:

- Senate Farm Bill assuming individual-level coverage selected in the Acreage Risk Coverage (ARC) program along with Supplemental Coverage Option (SCO) analyzed with the Food and Agricultural Policy Research Institute's (FAPRI) January 2012 Baseline projections of sector-level prices.
- Senate Farm Bill assuming county-level coverage selected in the ARC program along with SCO analyzed with FAPRI sector-level prices.
- House Farm Bill assuming Revenue Loss Coverage (RLC) selected and analyzed with FAPRI sector-level prices.

- House Farm Bill assuming Price Loss Coverage (PLC) along with SCO and analyzed with FAPRI sector-level prices.
- Stacked Income Protection Plan (STAX) for cotton was assumed to be in place for all farms growing cotton under both the House and Senate Farm Bills.

Simulation Results

Results were presented in terms of which types of farms preferred which farm program option. For example, the results for ranking the Senate bill are summarized in Table 1 in terms of the number of representative farms that preferred individual versus county-level coverage in the Senate bill. Based on the simulated net cash farm incomes (NCFI) for the farms, the majority of crop farmers would prefer the county yield option.

Figure 8 comes from the study and graphically portrays which farms would prefer the House bill and which would prefer the Senate bill. Icons for the types of crops and their locations were used to summarize the results graphically, in addition to using colors to indicate bill preference. Preferences were based on NCFI from simulating the alternative scenarios. The reports demonstrate that complex results can be presented in easy-to-understand graphics and tables for decision makers.

Table 1 Number of representative farms that would prefer individual versus county-level coverage based on NCFI in the Senate ARC Farm Bill package assuming FAPRI-projected prices

	Individual coverage	*County coverage*
Total by Preference[a]	22	40
Feedgrain/Oilseed	7	16
Wheat	3	8
Cotton	8	6
Rice	4	10

[a]Two farms, the small Texas southern plains cotton farm TXSP2500 and the Arkansas cotton farm ARNC5000, are 100% cotton and would only be enrolled in STAX. Therefore, there would be no difference between the alternatives.
Abbreviations: ARC, Acreage Risk Coverage; FAPRI, Food and Agricultural Policy Research Institute; NCFI, net cash farm incomes.

Investment Analysis

Investment analyses are a natural application of Monte Carlo simulation because investments always have risk and usually the investor is analyzing a business that does not exist but is being considered. For example, an investment in a new restaurant, or a new ethanol plant, or even a new feed store all have risks. Simulation is a systematic way to include risks from many different sources and to analyze the probability of the business being an economic success. The model for an investment decision is very straightforward; all it needs is the information to fill in an income statement, a cash flow statement, and a balance sheet for 5–10 years. (See the Appendix for a sample income statement, cash flow statement, and

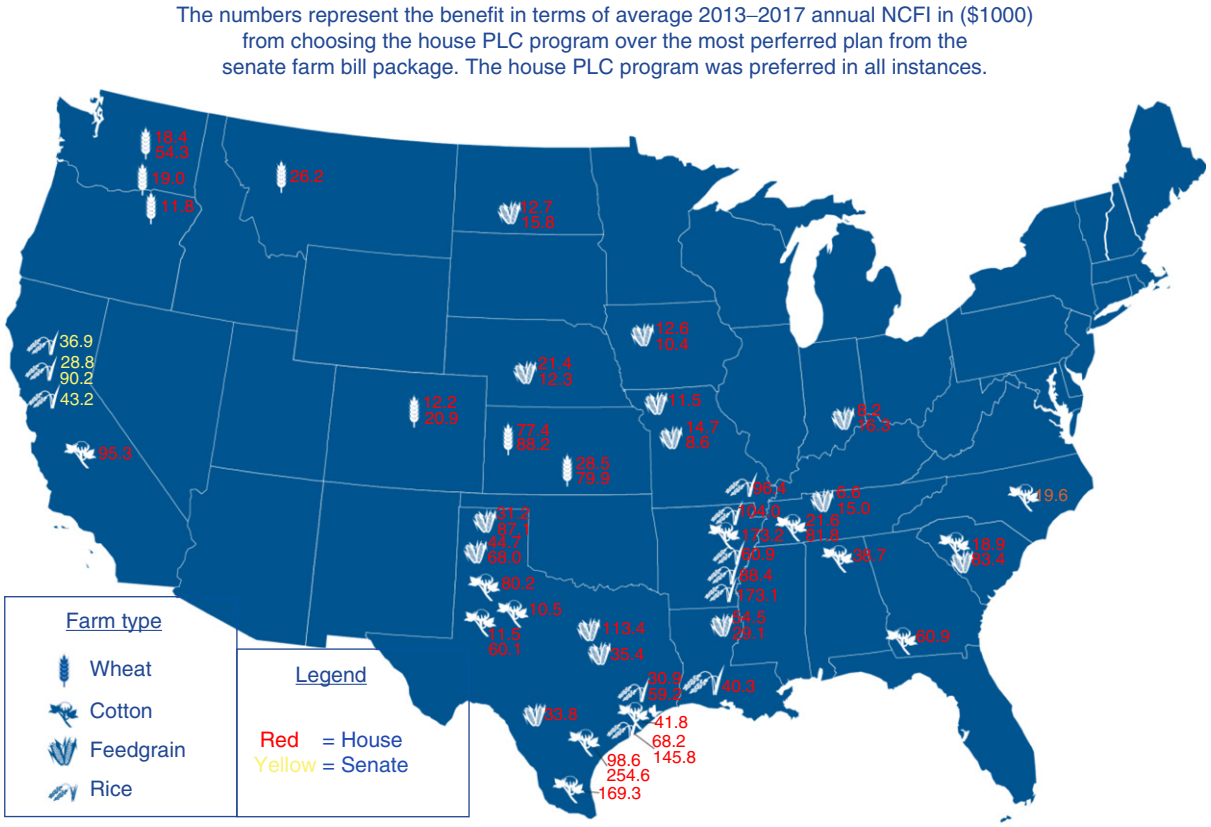

Figure 8 Results indicating the representative farm's preference for the House over the Senate safety net package.

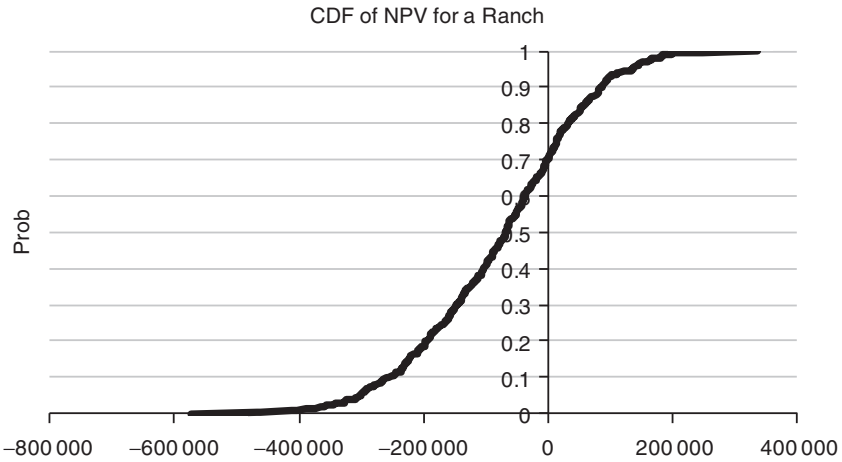

Figure 9 CDF of NPV for a ranch investment to demonstrate the probability of economic success.

balance sheet that would make up the majority of the equations for an investment model.) The stochastic variables are often a bit more challenging as they are distributions for prices of outputs, volume of sales, and costs of inputs or services provided.

The first investment simulation model developed by the author was for an ice plant (Richardson and Mapp, 1976). It was an early application for simulation of investments to appear in the agricultural economics literature and was the first to report a probability of economic success and a probabilistic cash flow. The probability of success was defined to be the probability of NPV being positive. The logic behind probability of success is that if NPV is positive, the investment generates a return greater than the discount rate, which is the investor's opportunity cost of capital. The investor in this case was concerned about the probability that cash flow from the business would be large enough to provide a minimum cash withdrawal, so the probability of positive cash flows was used by the decision maker for evaluating the investment.

A simple investment decision model is presented in this section to demonstrate how simulation can be used to evaluate a risky investment. The investment is a beef cattle ranch that has been in operation and the owner is considering selling the ranch and investing in a business that has an internal rate of return of 5%, so the discount rate is 10% for the problem. The ranch runs 500 mother cows and has an initial herd of 90 replacement heifers and 25 bulls. The ranch raises its own replacements by keeping 43% of the heifers each year. Risks on the ranch include: prices for cattle (culled cows, heifer calves, steer calves, culled replacement heifers, and culled bulls); price for surplus hay; and prices for buying deficit hay and soybean meal. Production risks include: hay yields, calving rate; death rates for calves, replacement heifers; and sale weights for heifers, steers, and culled replacement heifers.

The ranch has an initial net worth of $4.4 million and an expected NPV of minus $47 000. The probability of success from the stochastic analysis is 29% which can be read from the CDF for NPV in Figure 9. The summary statistics from simulating the ranch for 7 years are summarized in Table 2. The probability of NCFI being negative grows over the planning horizon as does the probability that EC is negative. Needless to say, the ranch as managed today is not a profitable investment. A deterministic analysis shows a positive NCFI and EC for the first 4 years and a slightly negative NPV. Without the stochastic analysis an investor would not know what a bad investment the ranch would make. A copy of the ranch investment model can be obtained from the author on request.

Insurance Analysis

Each year, crop farmers face with the problem of deciding whether to purchase crop insurance or not, and if they purchase an insurance, then what level of coverage to purchase. Crop insurance is quite complicated because it comes in many different levels of yield protection and the cost is associated with the level of coverage elected, and the premium subsidy decreases as the level of coverage increases. By definition, crop yields are risky, otherwise farmers would not be interested in purchasing insurance against low yields. In addition to crop yield insurance, farmers can also purchase a revenue insurance policy that insures against low yields and low prices.

A farm simulation model can be used to analyze the economic benefits of purchasing different levels of crop insurance. The model can be a simple model that just compares the economic returns for different insurance programs by simulating stochastic yields and indemnities and comparing the indemnities to the premiums for alternative policies. Or a complete farm simulation model can be used that has stochastic prices and yields for all crops and uses an income statement, cash flow statement, and balance sheet to show the economic consequences of alternative insurance policies on the economic viability of the farm. If a whole farm simulation model is available (see the Appendix), it is a simple task to add the formulas to calculate premiums and indemnities for crop insurance. The alternative policies being considered are simply programmed as scenarios and the model is run once for each insurance policy.

The results for simulating five alternative crop insurance options for a farm growing three crops are presented in this section. The NPV CDFs for the five insurance options are

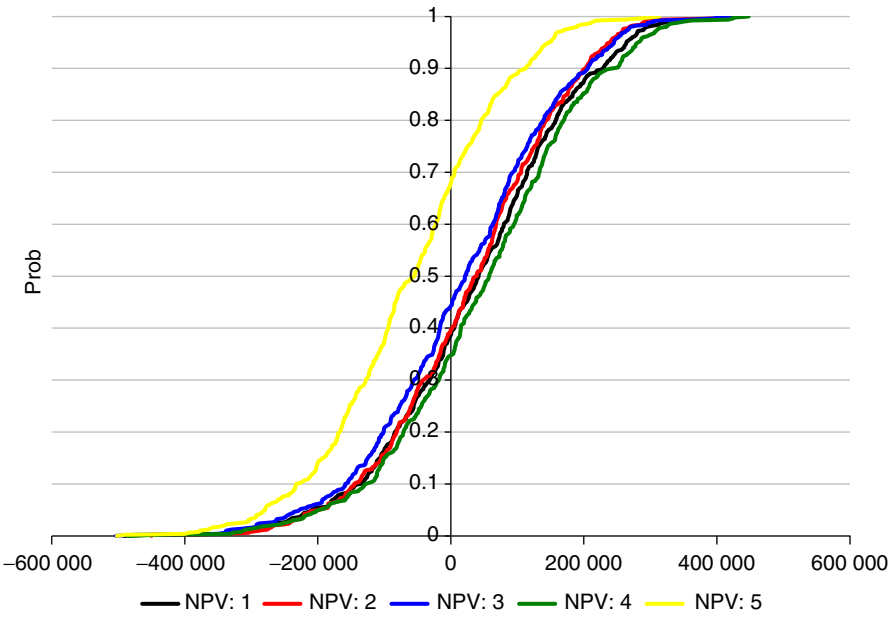

Figure 10 CDFs of NPV for five crop insurance options on a crop farm.

summarized in Figure 10. Scenario 5 is a no insurance option and is clearly the least preferred option. The CDFs for the insurance options cross, so that one cannot easily identify the best policy option for the farm. Stochastic efficiency was used to rank the risky alternatives for a range of relative risk-aversion levels that would likely fit the decision maker. The range of risk aversion was from risk neutral (relative risk aversion coefficient (RRAC) equal zero) to extremely risk averse (RRAC equal 4.0) in Figure 11. The power utility function was assumed for the analysis because the KOV used to compare the risky alternatives was NPV and it was calculated over a 5-year planning horizon. Based on the Stochastic efficiency analysis, the insurance policy associated with NPV-4 was the most preferred by all risk-averse decision makers because the certainty equivalents were greatest for this scenario across all RRACs.

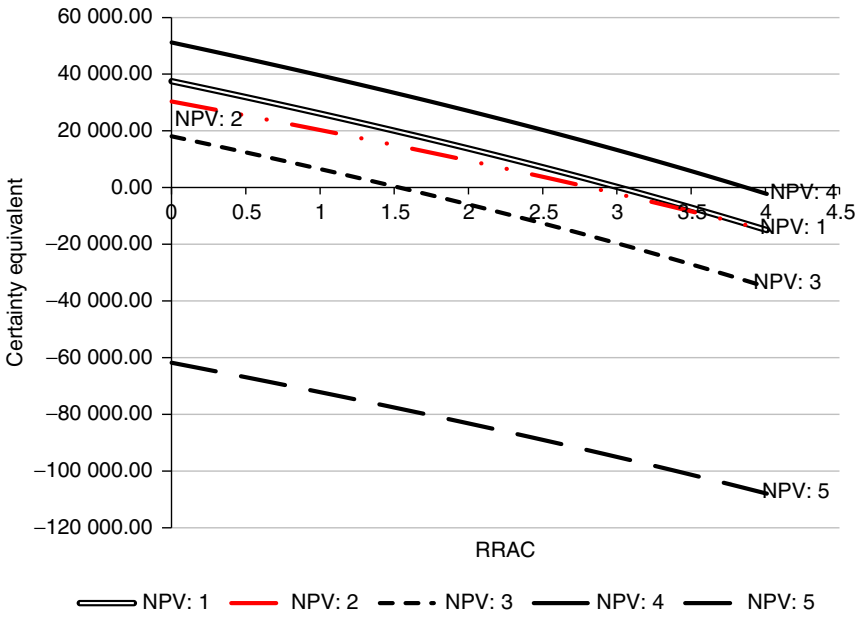

Figure 11 Stochastic efficiency rankings of five alternative crop insurance policies for a crop farm.

Technology Assessment

Technology assessment is another application of Monte Carlo simulation. In the case of technology assessment the task is two-fold: (a) prove that the technology is better than the existing technology and (b) calculating the value of the technology to the adopter so that the technology can be priced to extract the maximum rent to the technology owner. Technology assessments using simulation are not common in agriculture but can easily be done using simulation because technology is often introduced to reduce risk and reduce costs of production. If a technology is designed to reduce risk, then simulation that explicitly incorporates risk is the appropriate tool for assessing the benefits of the technology. Examples of risk-reducing technologies are: irrigation, drought-tolerant plant varieties, salt-tolerant crops, GMO crops, fertilization, and pest-control chemicals.

The example used here to demonstrate a simulation model to assess alternative technologies was developed at Texas A&M University for assessing the benefits of alternative technologies for small holder farms in developing countries. The economics model is part of the Integrated Data Support System which includes SWAT and APEX, which are biological models. APEX is a daily plant growth model capable of simulating a crop under alternative technologies using 30 years of weather data. The resulting output is 30 years of yields for a crop with an assumed technology/cultivation system. APEX's 30 years of yields are used to estimate probability distributions of yields for the base and alternative technologies that are used in the economics model.

The economics model, FARMSIM, simulates a small holder farm for 5 years using stochastic yields for the technologies being analyzed and stochastic prices for crops and livestock. Stochastic crop yields affect the quantity of feedstocks and pasture conditions for the livestock to the extent that forage from the crops are fed to livestock and pasture conditions are stochastic based on weather variability. Family consumption is restricted to raised crops and livestock products plus nutrients purchased using available cash. If cash is limited and raised nutrients are not available, the farm family suffers nutrient deficiencies. The KOVs in the FARMSIM model include the normal variables for NPV, NCFI, ending cash, and nutrient consumption for six nutrients. So, the FARMSIM model can show the economic and nutritional benefits of technology adoption for a family.

The results from simulating a small holder farm in Ethiopia are summarized in this section. The two technologies analyzed are: (a) use of irrigation and fertilizer and (b) use of irrigation plus adoption of fertilizer and improved seed varieties. A StopLight chart in Figure 12 shows the probabilities that the farm would have a cash flow shortage. There is a 34% chance of ending cash being less than 20 000 Birr in the Baseline and a zero chance of low ending cash under the two irrigation scenarios. Under the Baseline, the family's average daily consumption of energy is less than a minimum 11% of the time (Figure 13). This probability drops to zero for the alternative technologies due to increased production of food.

The value of the alternative technologies can be estimated using a risk ranking method called risk premiums. A risk premium is the difference in the certainty equivalents for the Baseline and an alternative technology. The certainty equivalents are calculated assuming a power utility function for all RRACs between risk neutral and extremely risk averse in Figure 14. The value of the irrigation and fertilizer technology is slightly over 30 000 Birr and by adding improved seed, the value of the technology is approximately 42 000 Birr over a 5-year planning horizon or almost 9000 Birr per year. The risk premiums are constant across the risk-aversion levels so that all risk-averse farmers would benefit equally from adoption of the two technologies.

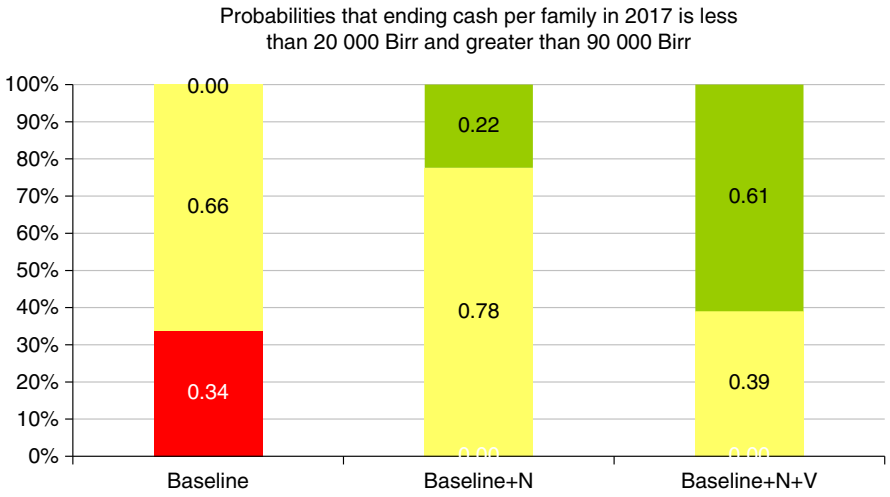

Figure 12 StopLight chart for comparing ending cash reserves under the base and two alternative technologies for a small holder farm in Ethiopia. Birr (Ethiopian Birr – Currency). N indicates the addition of fertilizer to its optimal level and V indicates the addition of improved seed technology through selective breeding for varieties adapted to the local conditions.

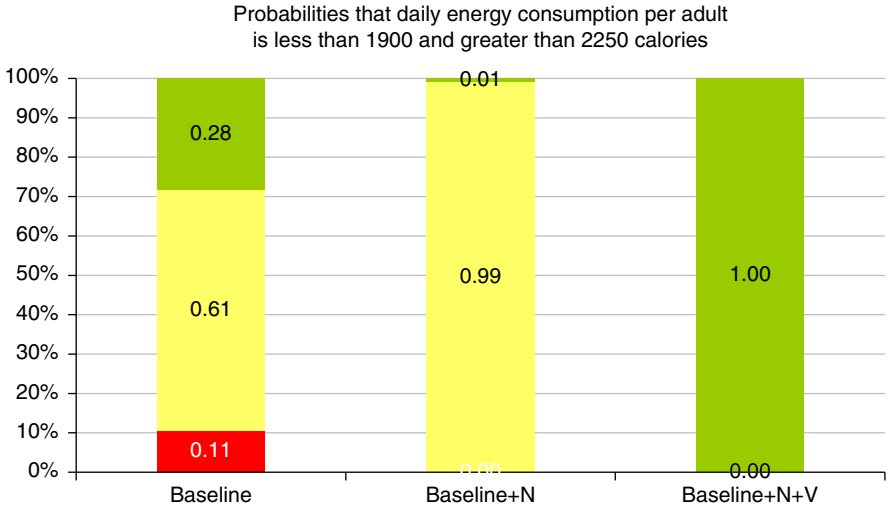

Figure 13 StopLight chart for comparing average daily consumption of energy for an adult equivalent assuming the base technology and two alternative technologies for a small holder farm in Ethiopia. N indicates the addition of fertilizer to its optimal level and V indicates the addition of improved seed technology through selective breeding for varieties adapted to the local conditions.

When simulating alternative technologies as demonstrated here, the risk premiums can be used to estimate the break point for pricing the technology. In the example shown in Figure 14, the value of the improved seed variety is approximately 6.3 Birr per hectare per year as the difference between the two risk premiums is 11 000 Birr (42 000–31 000) over 5 years and the amount of land the technology was applied to was 350 ha. Thus, a seed company wishing to value their improved seed could price the seed variety at some level less than 6.3 Birr and the producer would be better off than not adopting the improved seed.

Summary

Simulation is best suited for quantifying 'what if' questions and comparing probable outcomes for alternative actions. The brief description and examples of simulation analyses presented in this article should serve as a starting point for students and researchers interested in applying simulation to agricultural and natural resource issues. As demonstrated in this article, the introduction of risk into a simulation model is quite easily done and can be easily added to existing simulation models.

Agricultural and natural resource issues are particularly suitable for analysis with Monte Carlo simulation because of the strong influence of weather and price risks on agriculture. If one ignores risk in analyzing agricultural and natural resource issues, decision makers do not have a complete picture of the base situation or the projected consequences of actions they may undertake. Many decision makers are surprised when the outcomes they observe are different from the projections. Simply including risk in simulation models used for analyzing alternatives and making projection so that one can provide

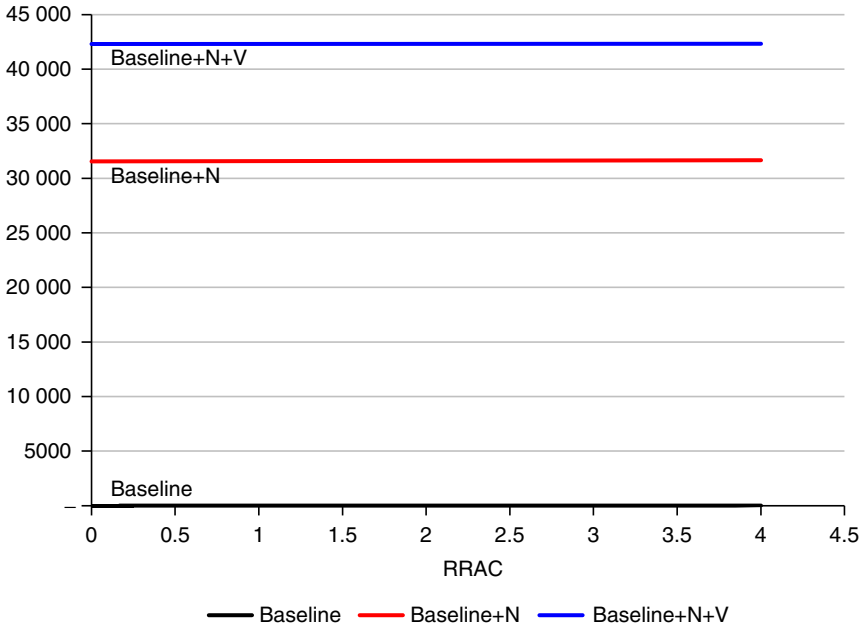

Figure 14 Value of technology for a risk-averse decision maker.

confidence intervals about the projections would help reduce the problem. Remember that, "point projections are always wrong, and projections presented in terms of a mean and a confidence interval are seldom wrong." Monte Carlo simulation is the tool for developing projections with confidence intervals.

Consumer-Oriented New Product Development

KG Grunert, Aarhus University, Aarhus, Denmark
HCM van Trijp, Wageningen University, Wageningen, The Netherlands

Introduction

For most companies, the introduction of successful new products is critical to the achievement of the short- and long-term corporate strategic goals of profitability, growth, and continuity. As an illustration, more than 25% of the current retail food sales in the US have been reported to consist of products introduced within the past 5 years (Hughes, 1994). Similarly, US marketing managers indicated that they expect 40% of the company profit made in 5 years' time would come from products not currently on the market (Booz *et al.*, 1982). Within the well-established product-market expansion matrix for growth (Ansoff, 1957), new product development (NPD) is identified as one of the important growth strategies of the firm.

Despite the fact that successful NPD is crucial to profitability and growth ambitions, the actual success rates of new product introductions are fairly disappointing. Although there is a lack of reliable data on actual success and failure rates, reported failure rates are ranging anywhere between 40% (e.g., Barczak *et al.*, 2009) and as high as 90% (e.g., Gourville, 2006). One reason for this lack of insight into actual success and failure rates stems from how success rates are being defined (Castellion and Markham, 2013). Success rates have been expressed as the percentage of commercialized new products that not only meet their marketing (e.g., market share and profit contribution) objectives, but also relative to the number of initial ideas that have entered the NPD selection process. Research on the 2003 the Product Development and Management Association best practices study (Barczak *et al.*, 2009) suggests that approximately 15% of the new product ideas and approximately 60% of the new products actually introduced into the market place make it to a commercial success in the market.

Whatever the exact metric and the exact percentage be, failure rates of new product introduction are an important concern to academics and practitioners alike, as new product introductions require substantial up-front investments that are not necessarily recouped from the new product's financial returns.

Bottom-line, NPD is an activity that is both necessary in light of market turbulence, but at the same time quite uncertain and risky in terms of potential failure. Not surprisingly, the NPD process has received a lot of attention in the marketing and management literatures (see Hart, 1996 for an overview).

New Product Development

NPD is an important activity within firms because of market turbulence; products do not have an infinite life. Rather, they go through a so-called product life cycle (PLC), which a company needs to anticipate to ensure that new products are added to the product portfolio to timely replace products that are nearing the end of their PLC. Also, NPD is identified as one of the basic growth strategies of companies.

Why New Product Development is Important

New product development as growth strategy

Early research by Ansoff (1957) suggested that growth strategies can be classified as to whether they use new or existing products and whether they address new or existing markets. Next to penetration strategy (increasing market share of existing products in current markets) and market development strategy (entering new markets with existing products), new product strategy involves developing new products for present markets and also plays a key role in the so-called diversification strategies where the company develops new products to enter new markets. Without new products, companies cannot grow over time as their existing products would gradually get 'outdated' against changing consumer needs and wants and new generations of products introduced by competitors.

Market turbulence

The need for NPD essentially arises from market turbulence on both the demand and the supply side (Van Trijp and Steenkamp, 2005). Consumer needs are subject to change over time, as are the specific ways in which consumers seek to satisfy these needs through the purchase and consumption of specific products ('demand'). Such changes may occur as a result of demographic, socio-economic, and cultural changes in society.

Turbulence also occurs at the supply side of the market. Changes in the political and legal environment trigger NPD through new requirements from (food) laws and regulations (e.g., increased minimal levels of animal welfare). Changes in the economic environment, such as increased or reduced purchasing power of consumers, will trigger innovation and development of new products that will deliver similar consumer benefits, but at a lower cost. Business strategies in terms of internal resources and business objectives also trigger innovation and predetermine in which categories and directions such innovation is to be found. Importantly, breakthroughs in (food) technology may provide new and unprecedented opportunities to both deliver new product-related benefits to the consumer and deliver existing benefits more effectively and efficiently. Finally, much of innovation activity is triggered by changes in the competitive environment, as new products introduced by competitors may change consumers' value perception of existing products in the market place. Together these developments create a highly dynamic context in which companies operate and compete for consumer loyalty.

The concept of product life cycle

A useful framework to think about the need for NPD is that of PLC. The concept of PLC implies that products, in terms of their sales and profits to the company, go through a four stage process (see Figure 1). At the introduction stage, sales are limited, costs per customer are high, and profit to the company tends to be negative as the necessary up-front investments in the new product cannot (yet) be recouped from sales and margins. At the introduction stage the clientele base for the new product primarily comes from the so-called innovator customers. At the growth stage of the PLC sales are rising not just among the segment of innovators, but also by attracting the so-called early adopters within the consumer population. At this stage of the PLC, companies attempt to increase their market share. Once a solid market share has been achieved, successful new products enter the maturity stage where profits increase and are managed. At this stage, the clientele base is expanded to include middle adopters, seriously reducing the costs per customer. But inevitably most products at some point reach a decline stage, where sales are declining because new products have already been introduced that more effectively or efficiently meet the (changing) consumer demand.

The importance of successful new product development

The concept of PLC nicely illustrates the importance of successful NPD. NPD activity requires substantial upfront investments which need to be recouped from the new product's performance in the market place. However, as is evident from Figure 1, it takes time before the product will take off, and generate sufficient margin and profit to compensate for the upfront investments. As a result, and in light of NPD failure rates, successful new products not only need to earn back their own investment costs, but also of those new products that fail to become successful. Next to the financial conditions, success in NPD also has an impact on the image of the company, as it makes the company more attractive to investors, but also helps to attract and retain creative employees. Successful NPD may help the firm to develop a learning curve on how to effectively synergize between the different functional departments of marketing, engineering, management, and production as well as sales. As an outcome of successful NPD, the firm may be able to create the so-called first mover barriers, for example, through patents that preempt competition from other companies trying to do the same thing.

Different Degrees of Innovativeness

New products introduced in the market place may differ considerably in their levels of newness, each with their own challenges and potential. Several classifications for innovativeness have been proposed, such as that between continuous (innovations with minimal impact on behavioral patterns of consumers), dynamically continuous (products with a higher degree of newness, but that still relate to products currently in use), and discontinuous innovations that violate some of the essential perceptions and habits and aim at creating new behavioral patterns on the part of the consumer (e.g., Gatignon and Robertson, 1991). A well-known classification from a company perspective is that of Booz *et al.* (1982), based on newness to the market and newness to the company, resulting in six categories.

At low levels of innovativeness, the category of 'cost reductions' involves new products that provide similar performance at lower cost, and the category of 'improvements and revisions of existing products,' similarly provide limited levels of newness in that they concern improved performance or greater perceived value with the aim to directly replace existing products. At medium levels of innovativeness, 'repositionings' also hold a limited level of innovativeness, as they are existing products that are repositioned to target new markets or market segments. 'Additions to existing product lines' carry a higher level of innovativeness in that these new products are designed to supplement existing product lines. They typically come as new flavors, new packaging (sizes), and the like. At the higher end of innovativeness, 'new product lines' bring a higher level of newness to the firm, but not necessarily to the market as such. New products aim to allow the company to enter an established market for the first time, and 'new-to-the-world products' are products that are so innovative that they actually

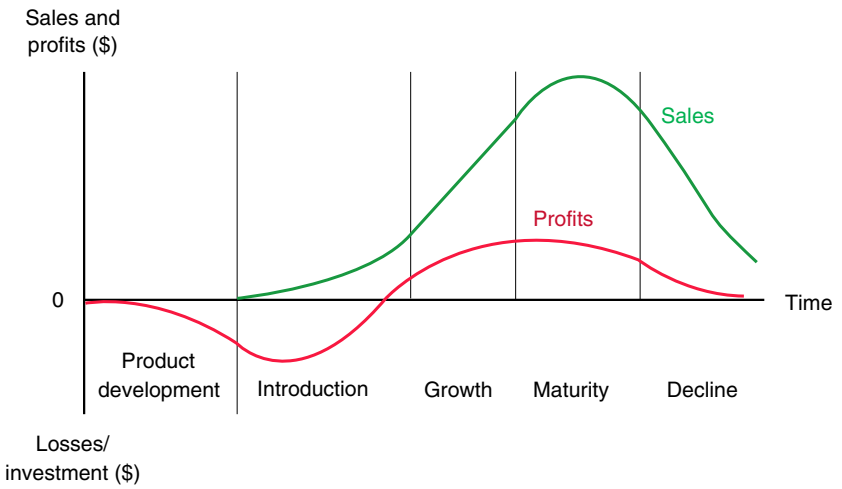

Figure 1 The product life cycle.

create a new market (Booz *et al.*, 1982). The vast majority of new products introduced in the market place involve improvements, additions to existing lines and product lines that are new to the company but not necessarily to the market. Importantly, the really innovative and new to the world products make up less than 10% of all NPD activity (e.g., Costa and Jongen, 2006), and the contribution of both this category and the new product lines category seem to be decreasing over time (Barczak *et al.*, 2009). Although there are no reliable figures for the level of innovativeness in food specifically, the situation in foods is unlikely to be very different. Food is seen as a traditional category with limited real breakthrough innovation.

Success and Failure Factors in New Product Development

There has been a lot of research into the success and failure factors of NPD. Much of this research is generic in nature with only a limited number of studies focusing specifically on NPD success factors in food (see Stewart-Knox and Mitchell, 2003; Kristensen *et al.*, 1998 for exceptions). Research on success and failure factors has essentially progressed along three dominant approaches.

Team performance approaches

Early work on the NPD process has focused on the use of structured processes for innovation management such as the stage-gate process. This line of research, popularized by Cooper and Kleinschmidt (1995), has taken NPD teams and their performance as the unit of analysis. For a wide variety of NPD teams, information has been collected on whether and how different steps in the stage-gate process were executed and at which level. This detailed information was then related to the NPD projects' market success, to identify crucial activities and performance that could differentiate the successful from unsuccessful projects. Based on this analysis, Cooper (1999) summarized the 'invisible success factors in product innovation' as follows:

- solid up-front homework – to define the product and justify the project;
- voice of the customer – a slave-like dedication to the market and customer inputs throughout the project;
- product advantage – differentiated, unique benefits, superior value for the customer;
- sharp, stable, and early product definition – before development begins;
- a well-planned, adequately resourced, and proficiently executed launch;
- tough go/kill decision points or gates – funnels, not tunnels;
- accountable, dedicated, supported cross-functional teams with strong leaders;
- an international orientation – international teams, multi country market research, and global or 'glocal' products.

Meta-analyses across scientific studies

A second approach takes the drivers of new product performance beyond team performance and process competencies, and uses scientific research publications as a basis. Through the so-called meta-analysis, consistency in reported relationships across different academic studies is extracted as a basis of strength of evidence for drivers of the NPD process. Henard and Szymanski (2001) differentiate between four broad clusters of drivers of NPD success, namely product-related factors (characteristics of the new product in terms of newness, sophistication, and product advantage), process-related factors (a structured NPD approach and proficiency in the various disciplines that need to be integrated for successful NPD), strategy-related factors (such as resourcing and cross-functional synergies), and market-related factors (such as competitive intensity and market potential). From these findings, Henard and Szymanski (2001) identified a more limited set of drivers that together account for no less than 59% of the explanation of innovation success. These factors are:

- product advantage (product related);
- product innovativeness (product related);
- marketing synergy (strategy related);
- technological synergy (strategy related);
- structured approach (process related);
- market orientation (process related);
- cross-functional integration (process related);
- competitive response intensity (market related).

A more recent update on Henard and Szymanski's (2001) meta-analysis (Evanschinsky *et al.*, 2012) confirms many of these success factors, but with smaller effect sizes and emphasizes the importance of culture as a moderator to the process, with generally weaker effect sizes for individualistic countries and stronger effects for risk-aversive countries. Product advantage, together with market orientation, comes out as the strongest determinants together with many process-related factors.

Monitoring of specific new products and their (marketing) context

A final approach zooms in more on the new product itself and the marketing context in which it is being positioned in the market place. For example taken by Steenkamp and Gielens (2003) and later extended to an international context (Gielens and Steenkamp, 2007). In this approach, 239 new product introductions in the consumer packaged goods sector were followed during 12 months period for their uptake in a household panel ($N=3687$). This approach takes four groups of determinants: marketing strategy (including relative newness and price), marketing communication (such as advertising and promotions), as well as product category-related factors (such as number of brands in the category, type of category, and advertising intensity in the category). Because the unit of analysis is household/consumer trial of the new product, this study also includes consumer characteristics (level of innovativeness and socio-demographics) as a determinant of new product success. Results on product-related factors are largely in line with those from other approaches, and confirm that the uptake of new products may differ between different consumer segments on the basis of their innovativeness as would be predicted from the product-lifecyle framework.

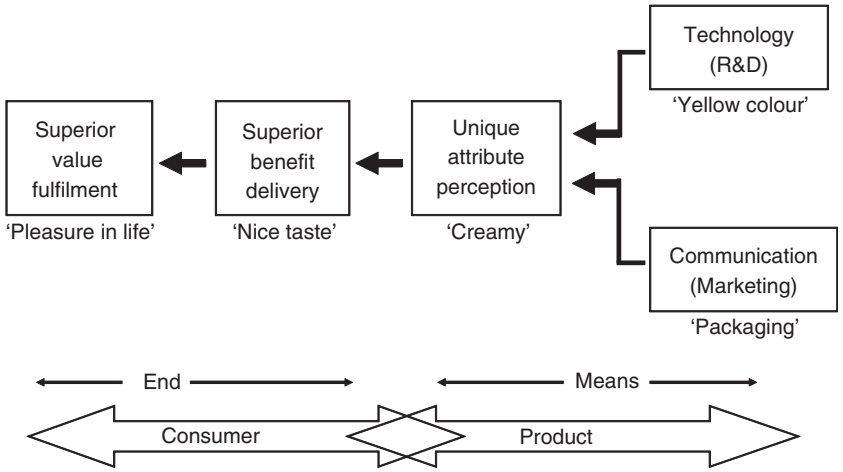

Figure 2 Products as a means to an end. Adapted from Van Trijp, J.C.M., Steenkamp, J.E.B.M., 2005. Consumer-oriented new product development: Principles and practice. In: Jongen, W.M.F., Meulenberg, M.T.G. (Eds.), Innovation in Agri-Food Systems: Product Quality and Consumer Acceptance. Wageningen: Wageningen Academic Press, pp. 87–124.

Integration of Success and Failure Factors

Although these three lines of research each take slightly different perspectives, they converge to a large degree, namely, that new products are more likely to be successful in the market place if:

- the product delivers something meaningful which is perceived of value by the consumer;
- in a way that is distinctive from competitive product offerings;
- the innovation is closely aligned to the capabilities of the company in that it synergizes between the marketing and technology competencies;
- the new product is brought forward through a well-designed and well-executed NPD process that is receiving sufficient support within the culture of the organization (market orientation).

Together these identified drivers of successful NPD form the basis of consumer-oriented NPD.

Consumer-Oriented New Product Development

The Essence of Consumer-Oriented New Product Development

Authors define consumer-oriented NPD as the challenge to the company to "optimally exploit and synergize its technological and marketing capabilities to deliver a distinctive product that is aligned to consumer needs and wants, with the aim to generate product trial and ultimately product loyalty" (cf. Van Trijp and Steenkamp, 2005). The latter addition is particularly important to the context of food and other the so-called fast moving consumer goods. Different from durable consumer goods, fast moving consumer goods are purchased and consumed (and hence re-purchased) on a regular basis. For such products the (product) quality experiences at the moment of consumption are critically important as they form the basis for the consumer decision to repurchase the product at a later stage.

New products as a means to an end

A key determinant of NPD success is the degree of fit between the new product and consumer needs (Grunert *et al.*, 1997). A useful framework to think of consumer-oriented NPD is that of means-end chain analysis (Gutman, 1982). Building on Lancaster's (1966) new consumer theory, means-end chain analysis assumes that consumers do not value products per se, but rather for the benefits that these products are believed to deliver on consumption. **Figure 2** illustrates this means-end chain perspective for a hypothetical case of mayonnaise. Technology can be exploited to change the color of the mayonnaise and marketing can be used to design an appropriate packaging (say glass jar). Consumers will interpret (perceive) these product features (say yellow color) by inferring attribute perceptions (e.g., 'the mayonnaise is creamy,' because consumers may infer that the yellow color comes from egg yolk which is believed to contribute to the creaminess of the mayonnaise). Such inferences in the form of attribute perception of the product may be relevant to the consumer, because he/she believes that creamy mayonnaises have better taste (hence superior benefit delivery). And finally, superior taste as a product benefit may, in the consumer's eyes, contribute to higher eating pleasure contributing to overall pleasure in life (superior value fulfillment).

Identifying these relevant links between product knowledge and consumers' self knowledge is central to means-end chain analysis and allows to understand why certain products are valued higher than others (Grunert, 2010; Gutman, 1997; Walker and Olson, 1991).

The process of linking product perception to consumers' value perceptions can be approached from different perspectives, sometimes referred to as different generations of innovation models (Berkhout and Van der Duin, 2007). A first generation of innovation, known as the 'technology push' model, started at the new technology side: new products were designed from technological opportunity and tested against

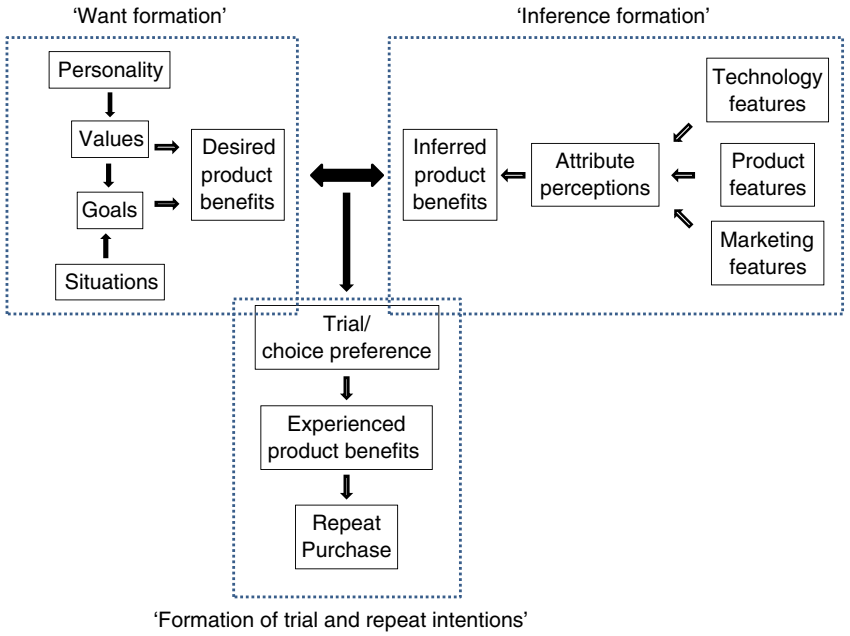

Figure 3 A simplified framework of how consumers decide on new products.

consumer perception and preference. The second generation started at the consumer side, also known as the 'market pull' model: if consumer needs and wants were understood, these could be reverse engineered into an optimal product design. The third generation, and also in line with consumer-oriented NPD as authors propose, attempts to find a more balanced input from both the consumer and technology sides throughout the process. This 'new' generation of innovation models takes consumer understanding as an integral part at all stages of a well-designed stage-gate process.

How Consumers Make Product Choice Decisions

Central to consumer-oriented NPD is the understanding of consumer behavior as the target of NPD success, next to technology and marketing understanding as a means to deliver a valued product proposition. Figure 3 illustrates a simplified representation on how consumer decision-making comes about as a function of three components: want formation, inference formation, and formation of trial and repeat purchases.

The architecture of the model is based on a simple marketing idea: consumers buy products not for their own sake, but because they think the product has characteristics that lead to desired benefits (Lancaster, 1966). This perceived match between wants and perception leads to preference and trial choice which, if delivering the promised benefits on consumption, will lead to repeat purchases. If the experience with the product after the first trial is positive, that is, the (new) product lives up to the consumer's expectations, the consumer may want to buy the product again.

The model has three major components: want formation, inference formation, and formation of trial and repeat intentions. Want formation deals with which benefits a consumer would like to obtain from a product at any moment in time, and this will be determined by both enduring personal (e.g., values) and situational factors (e.g., goals). Inference formation deals with how the consumer forms expectations about which attributes the product has and which benefits these attributes are believed to bring about for him/her inferred from available cues. Finally, formation of intentions for trial and repeat deals with how the comparison of wanted and inferred benefits leads, in comparison to the price of the product, to an intention to make a first-time purchase of the product, and how the subsequent experience with the product will affect intentions to keep on buying the product or not.

Consumers' want formation

The benefits that a consumer expects from a product are determined by both enduring and situational factors. Enduring factors are related to the consumers' values. Human values have been defined as "concepts or beliefs about desirable end states or behaviors that transcend specific situations, guide the selection or evaluation of behavior and events, and are ordered by relative importance" (Schwartz, 1992). Values are a popular and useful concept in the explanation of consumer wants, because they represent the ultimate human motivators with regard to a range of behaviors, including the purchase of products and services, and because there is a solid body of knowledge in social psychology on value types and their measurement. Various typologies of universal human values have been proposed, of which the one that has received most empirical support is the value domain model proposed by Schwartz (Schwartz, 1992; Schwartz and Bilsky, 1987). Schwartz proposes that human values can be grouped into 10 domains: power, achievement, hedonism, stimulation, self-direction, universalism, benevolence, conformity, tradition, and security, which can be grouped in a circular representation spanned by the axes of individualistic versus collective values, and conservative versus change-oriented values. The value domains are universal in the sense that they apply to all

human beings, but people will differ in the relative weight they attach to these values. Values have been used widely to explain consumer choices (e.g., Beatty *et al.*, 1985; Kahle, 1986; Kamakura and Mazzon, 1991), but their main advantage, namely that they are stable across situations and time, is also a disadvantage: abstract values, while often related to specific product choices, are relatively weak predictors of such specific behaviors, which are influenced by a host of other likewise more specific factors. Values provide the enduring motivational aspects of consumer wants, but to explain consumer choice, they will usually have to be supplemented by other factors taking into account situational factors.

Goals have a higher degree of specificity than values, and they have a situational component. When buying food, a consumer can have a goal of pleasing the family, of rewarding himself, of losing weight, or a host of other things. A goal of pleasing the family will be linked to underlying values, like benevolence and security, but will also have a situational component, as pleasing the family is not relevant, for example, when buying food in the canteen of one's workplace. Several goals can and mostly will be salient with regard to any particular food choice, and they can be in conflict with each other, such as when a goal of losing weight conflicts with a goal of rewarding oneself with a pleasurable experience. Developing products that solve goal conflicts is one important avenue to pursue in NPD in the food sector.

People differ in which goals are usually dominant when they choose food, and instruments have been developed to measure these differences and segment consumers accordingly. The food-related lifestyle approach has been a popular approach to this end (Brunsø *et al.*, 2004; Grunert *et al.*, 2001). Food-related lifestyle designates different ways in which people use food to attain life values and leads to generic consumer types that differ with regard to dominant goals and ways of shopping, meal preparation, and eating. The generic types identified are the uninvolved consumers, who are really not very interested in food, the careless consumers, who emphasize novelty and convenience, the conservative consumer, who puts priority on traditional meals and generally uses eating to establish a sense of security, the adventurous consumer, with an emphasis on social and innovative goals in preparing and eating meals, and finally the rational consumer, who has a reasoned approach to food choice and values healthfulness highly. This instrument has been popular in Europe and has even been applied in China (Grunert *et al.*, 2011).

Goals thus point at desired benefits that the consumer wants to get out of the product to be bought. Desired benefits can be many things, but from social dilemma theory (Van Lange *et al.* (2013) and Construal Level Theory (CTL) (Trope *et al.*, 2007), it is suggested that they can meaningfully be classified as to whether they deliver benefit to the self or to others, and whether they deliver direct gratification or delayed gratification (e.g., Van Trijp and Fischer, 2011). Directly gratifying self-oriented benefits include the sensory properties of the food, its convenience, and its price. Self-oriented delayed benefits include the health value of products. Other-directed benefits with relatively direct reinforcement value include motivations of local production to stimulate regional economic development and animal welfare motivations. Delayed, other-directed benefits include sustainability considerations and the impact of new food technologies on the environment and impact on society.

Research from the CTL tradition suggests that self-oriented benefits that deliver instantaneous gratification ('feasibilities') are more likely to be driving forces in situations of low psychological construal (such as the choice situation), whereas preferences for other-directed benefits with delayed gratification (the 'good intentions') take priority in situations of high psychological distance (such as in survey situations). Thus, identifying desired benefits in any particular situation is a methodologically challenging task.

Consumers' inference formation

To infer whether any of the available products matches the desired product benefits, the consumer makes inferences about the available options in the product assortment. This is the process of inference making and benefit perception (Kardes *et al.*, 2004). Based on the characteristics of the product as delivered by its features, description, and positioning, consumers will extract attribute perceptions from which expectations are formed, in a means-end framework, regarding the benefits that the product will deliver. Such benefit inferences carry a degree of uncertainty. In many instances these inferences can build on product associations that are learned from previous experience. Product benefits for which this is possible are known as experience qualities of the product (e.g., Steenkamp, 1990). If a product has delivered good taste, convenience in use and other benefits that are directly perceivable on consumption, this will strengthen the expectation on the next consumption occasion. For many product qualities, the so-called credence qualities (Darbi and Kerny, 1973), such learning from experience is however not possible. For example, to what extent a product delivers health, sustainability, or animal welfare, cannot be verified from personal experience, not even after normal consumption. Yet, consumers form beliefs about such credence qualities through two important psychological processes, known as informational and inferential belief formation (Fishbein and Ajzen, 1975). In information belief formation, consumers make inferences from information provided by relevant and authoritative others, such as through the use of labels, claims on the packaging, and recommendations from, for example, consumer organizations. In inferential belief formation, consumers use their own rules of thumb in what they believe are informative relationships. As a result, packaging cues such as color (say green) may trigger inferences about credence quality attributes such as that the product is probably natural and sustainable. Inferential belief formation based on the so-called quality signals or quality cues (Grunert, 2005) constitute an important consumer strategy when the benefits expected from the product are unknown, and when previous experience is of no help.

The way in which consumers make inferences from quality cues will not necessarily lead to 'correct' inferences in the sense that they will correctly predict the benefits that the product will deliver. For example, consumers are known to use color and fat content of meat as an indicator of taste and tenderness (Brunsø *et al.*, 2005) and organic production as an indicator of superior taste of vegetables (Padel and Foster, 2005). Both of these inferences are, from an objective point of view, at least questionable. Consumers' ability to make such inferences will

depend on their level of knowledge and competence with regard to the product (Selnes and Troye, 1989). When asking consumers which information about a piece of meat they believe to be predictive of taste and tenderness, many consumers believe that information about breed, age of animal, and slaughtering date are predictive of these qualities. But few consumers feel confident in using them, i.e., making the right inferences based on this type of information, because they are not meat experts. Thus, consumers end up making inferences based on cues with which they feel confident, like color of meat and visible fat content, even though they may be aware of the fact that these characteristics are not always highly predictive of taste and tenderness. Such inferences can be deliberate, but often they will be done in a semiconscious, almost automatic way.

Inference processes are getting more complex as new products carry more and more information. A new product that comes on the market will have a brand name, carry nutritional information, may have quality marks and sustainability labels, and carry nutrition and/or health claims. This information may be supplemented by soft claims like the product being natural or good for you, and all this will be embedded in packaging that makes use of colors, pictures, and various stylistic elements. It is the complete array of this, together with the context in which the product is displayed and promoted, that forms the basis for consumer inferences.

The way in which consumers make inferences about product benefits from available cues is based on consumers' product knowledge. When combine consumers' product knowledge, i.e., knowledge about how to infer product benefits from an array of cues, with consumers' knowledge about themselves, i.e., with knowledge about how product benefits will help them attain their goals and values, a complete means-end chain is obtained, as shown in Figure 2. A means-end chain is thus a device to show how consumers become motivated to buy a product based on the combination of knowledge about the product and knowledge about oneself.

Formation of trial and repeat intentions

The extent to which the product benefits that consumers infer from a new product will have matches with the benefits that they desire will be related to the consumer's willingness to try the product, i.e., buy it for the first time. However, the perception of benefits will lead to purchase only when the benefits are perceived as high enough for the consumer to be willing to pay the price demanded in the shop. Measuring willingness to pay and how willingness to pay depends on product characteristics is an established research area in agricultural economics and marketing, and a range of methods is available to this purpose (e.g., Miller *et al.*, 2011). In determining willingness to pay, consumers will try to find points of comparison. Consumers may be familiar with average prices in the product category of which the new product is a member, and will then usually use these as a benchmark. If the new product has an above-average price within the category, willingness to pay will depend on whether the expected benefits clearly exceed the benefits of those products that are already on the market. For a product with a high degree of innovativeness, categorization into an established category may be more difficult and reference prices hence also more difficult to base a judgment on, but consumers will in most cases try to find some point of comparison based on previous experience that allows them to come up with a judgment on the price of the product.

After a product has been bought once, the consumer will have an experience with the product, and this experience will have an important influence on whether the consumer wants to buy the product again. Because, as already noted in the Section Consumers' inference formation, only some benefits that a consumer may expect from a food product can in fact be experienced, mostly taste and convenience, authors may tend to conclude that the decision on whether to buy the product again will depend mainly on the experience with these particular benefits. To a large extent, this is true: a product with a bad taste will not usually be bought again, in spite of other benefits in terms of healthfulness and sustainability. Also, there is evidence that the relative weight of those benefits that indeed can be experienced increases after the purchase at the expense of those that cannot be experienced. In other words, after consumption, taste plays a bigger role in the evaluation of the product compared to healthfulness, than before the purchase. However, the mechanisms at work are more complicated. When a range of competing products do not differ a lot in terms of taste and other benefits that can be experienced, the more intangible benefits will play a larger role, also when it comes to repeat purchases. Inferences in the prepurchase phase and perceptions in the consumption phase may influence one another, such as when a consumer believes that an organically produced product indeed has a better taste than competing products with an identical sensory profile, simply because this is what was expected and the experience is assimilated toward the expectation. Also, during preparation and consumption, new cues may arise that can strengthen or weaken the consumer's perception of the presence of benefits that cannot be experienced. For example, the consumer may think that the feel of the packaging is not very sustainable, or that the taste of the product indicates that it may after all not be very healthy.

The sensory experience with the product, together with convenience, are therefore still decisive for whether a trial purchase of a new product turns into a repeat purchase. But this is mainly a factor that can prevent a repeat purchase, if the product clearly disappoints in terms of taste and convenience compared to competing products. An acceptable taste may not be enough to encourage repeat purchase in an era where new food products are increasingly positioned in terms of intangible benefits like healthfulness, sustainability, naturalness, and authenticity. These benefits being intangible, not amenable to experience, implies that food manufactures need to ensure that the belief in these benefits is kept alive in the mind of consumers throughout repeat purchases, to prevent that these benefits are, over time, crowded out in the mind of the consumer by the more tangible benefits.

Integrative Approaches to Consumer-Oriented New Product Development

The consumer decision-making process, described in the Section How Consumers Make Product Choice Decisions, forms the heart of consumer-oriented NPD, where the aim is to design new products (product and technology features) and to

position these in the market place (marketing features) in a way that they are aligned with consumer-desired benefits in a distinctive way, such that trial (from product quality expectations) and repeat purchase (from experienced product quality) is induced.

This is a challenging task that requires close interaction between the technological and marketing/consumer science capabilities within the company. Market orientation plays a crucial role in this process.

Market orientation

The importance of market orientation as a driver of company performance and success in the market place is one of the best established findings within the marketing literature (see Kirca *et al.*, 2005 for a review). Market orientation involves the organizational norms and values to behave consistent with market orientation, as evidenced in closely monitoring customers and competitors with a focus on inter-functional coordination within the company (Narver and Slater, 1990). The behavioral perspective on market orientation (e.g., Kohli and Jaworski, 1990) emphasizes the activities of generation of information about customers and the market place, the dissemination of this information across different functional disciplines within the company, and use of this information as a basis for a coordinated and responsive marketing approach and market offering. Market orientation enhances a company's performance through a higher level of innovativeness, which serves as a basis for customer loyalty and perceived product quality delivered to the market place (Kirca *et al.*, 2005). Market orientation has both a responsive (aligning with existing consumer needs and wants) and a proactive (addressing latent and emerging consumer needs) component to it (Narver *et al.*, 2004), and hence forms a strong basis for NPD.

Quality function deployment as an overarching framework

Dissemination of customer information across the functional disciplines, and particularly between the marketing and technology departments, is crucial to designing an optimal response in the form of new product introductions. However, such effective communication between the marketing and technology disciplines within the company is often poorly developed (Atuahene and Evangelista, 2000) and a source of NPD failure (Souder and Chakrabarti, 1978).

Quality function deployment (QFD) has been proposed in the early 1970s as a highly structured planning tool to make explicit the 'translation' process of relating consumer and customer inputs to technical design parameters and product requirements. QFD has been applied in many different industries (Hofmeister, 1991), including the food industry (e.g., Costa *et al.*, 2001). QFD consists of four modules of which the first one, the so-called House of Quality, has most relevance for consumer-oriented NPD (e.g., Hauser and Clausing, 1988), as it specifically focuses on the translation of consumer choice criteria into (technical and marketing) product design parameters. **Figure 4** provides a simplified version of the House of Quality.

The House of Quality structure integrates the key questions that form the heart of NPD as will be outlined below, referring to numbering in **Figure 4**.

1. What are the product characteristics desired by the consumer? This 'box' refers to the identification of the key needs and desires that drive consumer choices in the product category. It includes those desires that are necessary to meet and surpass competition and those on which the new product will have improved or unique delivery. Marketing and consumer research are the key tools for identifying the consumer needs and desires as well as their

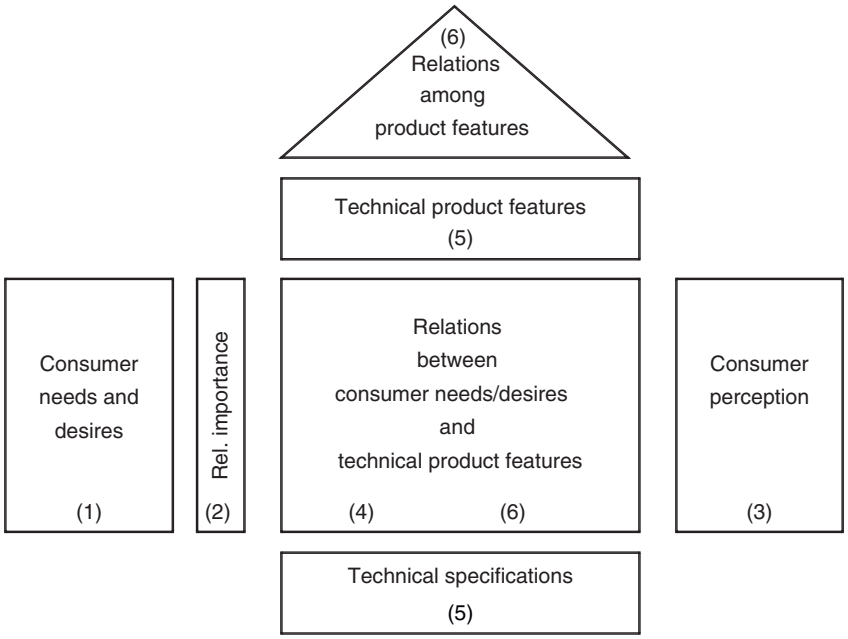

Figure 4 The House of Quality within Quality Function Deployment. Adapted from Van Trijp, J.C.M., Steenkamp, J.E.B.M., 2005. Consumer-oriented new product development: Principles and practice. In: Jongen, W.M.F., Meulenberg, M.T.G. (Eds.), Innovation in Agri-Food Systems: Product Quality and Consumer Acceptance. Wageningen: Wageningen Academic Press, pp. 87–124.

hierarchical nesting. Several techniques are available for this purpose (see Griffin and Hauser, 1993 for an overview), including exploratory qualitative techniques such as in-depth interviews and focus groups as well as more structured approaches such as Kelly's Repertory Grid and Free Elicitation (see Steenkamp and Van Trijp, 1997). A particularly useful technique for revealing the hierarchical nesting of need levels within the means-end chain paradigm is that of laddering (Reynolds and Gutman, 1988).

2. How important are each of the product characteristics to the consumer? Box 2 recognizes that some needs may be more important than others in driving consumer choice within the targeted product category. Identification of attribute important is a crucial step in QFD as any company will prefer to spend its limited resources where they matter most to the customer. Attribute importance is a complex and not always well-defined concept, for which a number of measurement methodologies are available (Van Ittersum *et al.*, 2007). An important distinction needs to be made between attributes that are important in an absolute sense and those that are determinant in consumer choice behavior, as some attributes are a 'conditio sine qua non.'
3. Will adjustments on a consumer attribute lead to competitive advantage? This box addresses the issues of whether changes introduced through the new product will be recognized by the consumer as a competitive edge vis-à-vis competing products already in the market place. Marketing and consumer research are conducted here in the form of the so-called quantitative perceptual mapping techniques (Urban and Hauser, 1993; Steenkamp *et al.*, 1994; Steenkamp and Van Trijp, 1996b). Perceptual mapping research identifies how the consumer perceived product alternatives on key attributes.
4. What are the implications for technical adjustments to the product? The so-called relationship matrix forms the heart of the House of Quality in that it links "what the product is aimed to deliver" (the marketing opportunity) to "how this can be realized" (the product design) in the form of engineering characteristics of the new product. At this stage, relationships are established on how product design features affect consumer perceptions and need satisfaction, and if so how strong these relationships are. Typically these relationships are not of a one-to-one nature, as multiple engineering characteristics combine and interact into a consumer perception of the product. Also, and particularly in the food domain, these engineering characteristics are not orthogonal implying that they cannot necessarily be manipulated independently of each other. These correlations between the engineering characteristics are reflected in the 'roof' of the House of Quality. A statistical implication of the dependence between engineering characteristics is that complex multivariate statistical methods are required for the translation process from marketing opportunity to new product design as reflected, for example, in the Quality Guidance model (Steenkamp and Van Trijp, 1996a).
5. Do consumer attributes have physico-chemical counterparts? Once the relationships have been established, profiling a selection of potential new product alternatives in terms of their engineering characteristics is an integral part of the analysis. Together with insights into the consumer perceptions, this provides highly diagnostic information. For example, a situation may occur where two products show differences in consumer perception (box 3) but not in terms of engineering characteristics. In such case, the new product design needs to be complemented with marketing communication and positioning to realize the desired product image and to gain competitive advantage in the market place.
6. What is the effect of technical adjustments on other consumer attributes? As a final step, this box brings into the picture to what extent technical improvements on one consumer attributes may go at the expense of consumer perception and delivery on other relevant consumer attributes. This step is often overlooked because of some degree of product myopia. For example, reducing the salt levels in a soup will improve the healthfulness of the product, but at the same time may also negatively impact on the (perceived) taste of the product. Such trade offs need to be carefully considered in the process of new food product development.

In summary, QFD provides a highly structured framework for identifying the relevant relationships in the process of translating new product opportunity to product design. However, the structured nature is both a strength and a weakness. Particularly in the food context the product characteristics and design features often interact in highly complex ways and can rarely be manipulated independent of one another. This may partly explain, why QFD has been influential in the food sectors as a thought process, but not as an actual practice. Nevertheless, QFD has served as an important source of inspiration to food-specific quality perception models as a basis for new food product development, such as the Quality Guidance Model (Steenkamp and Van Trijp, 1996a) and the Total Food Quality Model (Grunert *et al.*, 1996).

Structured Approaches to New Product Development

NPD success strongly benefits from the adoption and execution of highly structured innovation processes, with continuous feedback on (anticipated) consumer response. Most innovation projects follow the general NPD stage-gate process, consisting of a number of phases after every of which a go-no-go decision is made on the basis of relevant feedback from the market place.

The New Product Development Stage-Gate Process Model

Structured approaches to NPD conceive it as consisting of a number of phases or stages (Trott, 2008), although the exact number and the naming of the stages differs. Authors follow Van Kleef *et al.* (2005), who distinguish between the stages of opportunity identification, development, optimization, and launch. Structured processes as particularly important as they identify the critical steps in moving from initial idea conception all the way through to the actual 'product as marketed' being launched into the market place. Up-front investment costs to the company increase from the left to the right of the

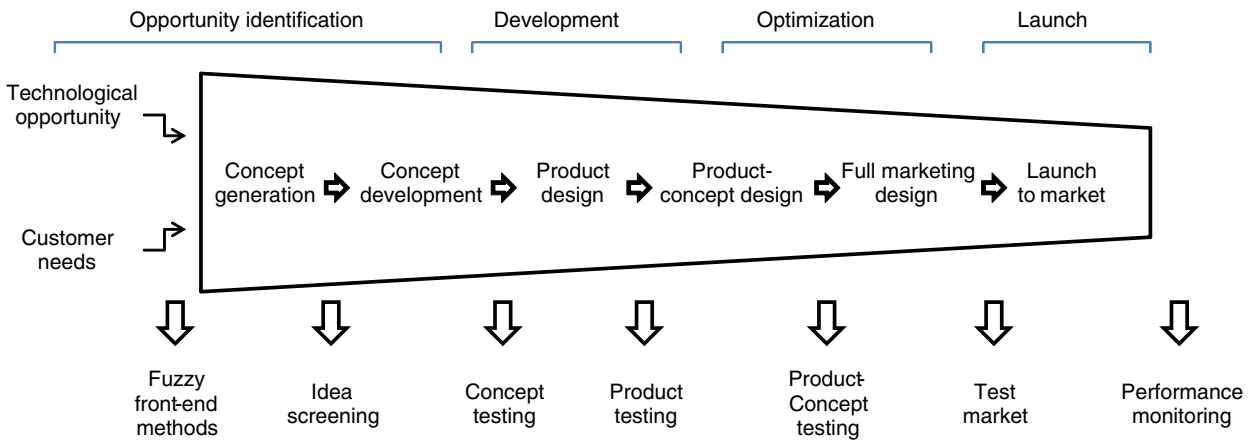

Figure 5 The formal stage-gate process to NPD.

stage-gate process and hence also the (financial) risk to the company. This is why 'gates' are introduced in the process at which the feasibility of the new product, in different stages of development, is critically assessed and reviewed. Crucial stages in the process, where costs increase sharply are the actual development process (i.e., product design), the full marketing development, and the market launch stage.

Figure 5 represents the stage-gate process, including the activities and the critical gates which are implemented through consumer/market testing. First, new market opportunities have to be identified from both understanding of consumer and customer needs as well as new technological opportunities. From this, new product ideas are being developed and screened for their potential to the company, including their technical and economic feasibility. From this insight, product concepts are being developed which essentially reflect a very concise description in consumer terminology of the product's core benefit proposition: "the unique benefits that the product is to provide to customers as well as those benefits required to meet and surpass competition" (Urban and Hauser, 1993, p. 164). If the results from concept testing are promising, the new product may actually be designed; first as a product prototype and later in combination with its intended positioning in the market place (product-concept design). If product and product-concepts tests with customers and consumers yield positive results, the marketing mix of the product may be further developed, including the packaging and the advertising materials. In some specific situations, the product may then be tested in a test market (either real or experimental) as a basis for the final product launch into the market place.

Consumer research for the stage-gate process

Consumer research methodology for most of the gates in the stage-gate process is well developed and documented, particularly for the design and optimization stages (e.g., Ozer, 1999; Kaul and Rao, 1995; MacFie, 2007), with the aim to screen out new product ideas, concepts, and prototypes that may be unsuccessful in the market place. However, increasingly it is being recognized that NPD effectiveness and efficiency relies as much on 'screening-in' promising ideas and opportunities upfront (known as the 'fuzzy front end of innovation') as it does on 'screening-out' options during later phases.

Consumer input at the fuzzy front end has been challenged by some authors on the argument that many existing consumer research techniques are better equipped for measuring consumer response to presented new product ideas (i.e., product screening) rather than for using consumers as a source of new idea generation (Eliashberg *et al.*, 1997). Mainstream consumers are seen as a poor source of inspiration and creativity, because of their 'status-quo bias,' through which their thinking is heavily restricted by their current experiences (e.g., Lilien *et al.*, 2002). Yet, all research on NPD success indicates that 'bringing the voice of the customer upfront' already in the fuzzy front-end of NPD is an important success factor. Selection of market and consumer research methodologies at the fuzzy front end of NPD is hence crucially important, and a variety of research methods are available to enhance actionability without limiting creativity (Van Kleef *et al.*, 2005).

Consumer acceptance of new products

More generic research on consumer acceptance of innovations and new products largely originates from the early work by Rogers (1995). Rogers identified five the so-called innovation characteristics, perceived product attributes of an innovation, which affect the rate of adoption of new product innovations. These innovation characteristics are as follows:

- relative advantage: the degree to which the innovation is perceived as better than the product it replaces;
- complexity: the degree to which an innovation is perceived as difficult to understand and use;
- compatibility: the degree to which an innovation is perceived as being consistent with the existing values, past experiences, and needs of potential adopters;
- trialability: the degree to which an innovation may be experimented with on a limited basis;
- observability: the degree to which the results of an innovation are visible to others.

All five factors are highly relevant to the acceptance of new food products and particularly the first two factors have become central to the research tradition of Technology Acceptance Models (e.g., Venkatesh *et al.*, 2003), where they have be

relabeled as 'Usefulness' and 'Ease of Use.' This research confirms that innovation are more likely to be accepted and adopted by end user, if they add value over and above the products currently in use, and are easy to understand and use.

However, in the specific case of new food products, aspects of compatibility play an important role too, next to relative advantage and (low levels of) complexity. A first reason why compatibility is important in new food product acceptance is that new (an unknown) technologies applied to foods, which are actually ingested into the human body, are often approached with reluctance on the part of the consumer (Siegrist, 2008; Ronteltap *et al.*, 2007). This is not because of product performance-related inferences but because of socio-political attitudes that consumers hold with the technology (Frewer *et al.*, 2004; Scholderer and Frewer, 2003). Importantly also, food behaviors have a strong cultural and habitual component to them, which makes consumers reluctant to accept new products that require adjustment in existing food routines (e.g., Van Trijp and Van Kleef, 2008). Hence for new food products (e.g., Rozin, 1976), generating consumer acceptance may even be more challenging than for products outside the food domain (Szymanski *et al.*, 2007).

Concluding Remarks

As started off this article by stating that NPD is a necessary yet high risk activity for the firm. However, throughout this article it has been argued that this risk can, at least to some extent be managed. Authors provided evidence that consumer relevance of the product advantage and market orientation throughout the process are key identified factors for NPD process. Authors developed a simplified model of how consumers make decisions regarding (new) product decisions, and used this as a basis for consumer-oriented NPD. Incorporating this consumer perspective throughout a structured and well-executed NPD process enhances the changes of NPD success.

Glossary

Case of illness An individual person who acquires a disease or illness associated with an epidemiologically significant exposure.
Critical Tracking Event A physical point in the food supply chain where an operator identifies a minimum set of event data to systematically collect, typically consisting of three basic data items: unique location/Event ID, unique Item ID, and date/time.
Food supply chain A sequence of processes involved in the production and distribution of food.
Global Trade Identification Number (GTIN) An identifier for trade items used to lookup product information in a database or between databases.
Hazard analysis critical control points A systematic preventive approach to food safety and allergenic, chemical, and biological hazards in production processes that can cause the finished product to be unsafe as well as designs measurements to reduce these risks to a safe level.
Key data element A set of data, defined by a food operator, associated with a Critical Tracking Event.
Product case It is typically the smallest logistic unit in consumer supply chain; a cardboard box or container holding individual consumer units for sale in a retail setting.
Universal Product Code (UPC) A barcode symbology used to track trade items in stores.

Introduction

Foodborne outbreaks represent a significant burden of illness in the United States and internationally causing significant morbidity and mortality (Scallan *et al.*, 2011; Kuchenmüller *et al.*, 2009). Although the majority of these illnesses are of an unknown etiology, a significant number are associated with commercially distributed foods. As the complexity and speed of the food supply increases, private industry, government regulators, and public health officials have been challenged in tracing potentially implicated foods during and after foodborne illness outbreaks. Notable examples include outbreaks associated with spinach, peanut butter, shell eggs, fresh produce, and pet food (Wendel, 2009; Medus *et al.*, 2009; Cavallaro *et al.*, 2011; Braden, 2006; Anonymous, 2010).

As a result of these outbreaks, improved recordkeeping and traceability requirements were included in the landmark passage of the Food Safety Modernization Act in January of 2011. This Act specifically required the Food and Drug Administration to establish pilot projects to explore and evaluate methods to rapidly and effectively identify recipients of food to prevent or control a foodborne illness outbreak.

Surprisingly to many, the primary goal of food traceability is not food safety. The primary goal of food traceability is to improve investigational efficiency. Specifically, the goal of improving food traceability is to improve the speed of investigations as well as the accuracy of results. Therefore, the problem of food traceability requires a mindset that is first rooted in logistics rather than food safety. Certainly, achieving improvements in food traceability will more likely result in fewer cases of foodborne illness, reduction in the amounts of otherwise wholesome foods discarded, as well as added protection of industry segments and/or product brands from erroneous implication in outbreaks. Also, increasing the number of successful outbreak investigations will lead to more opportunities to learn from mistakes, resulting in accelerated improvements to food safety throughout the supply chain. Therefore, increased food safety is a likely but indirect benefit of improvements in logistic performance related to food traceability.

Although the link between food traceability and food safety exists, there are a few layers of activity, action, and investment required to better secure that linkage. Historically, the food industry and the FDA have tended to view food traceability exclusively through the prism of food safety rather than logistics and that may have slowed innovation and adoption of effective food traceability solutions. Food safety tends to involve conditions of handling, processing, and production as opposed to movement of products through the supply chain. Specifically, food safety is a quality function, whereas food traceability is a logistic one. Although safety is always a concern with food, logistics involves a different perspective, different skill sets, and different tools than production-oriented quality control and assurance.

Currently Accepted Concepts for Food Traceability

Based on current regulatory requirements to maintain one-forward-one-back (OFOB) traceability documentation (Anonymous, 2002), most supply chain participants are comfortable with the concepts of 'internal' and 'external' traceability. However, traceability requires that linkages through each operation are maintained, so these definitions of 'internal' and 'external' are not particularly useful in trying to comprehend the problem and possible solutions. Some operators argue that this definition is necessary to protect internal proprietary information, but authors will show this to be unfounded. By focusing on solving 'external' traceability at the expense of 'internal' traceability, effective traceability solutions

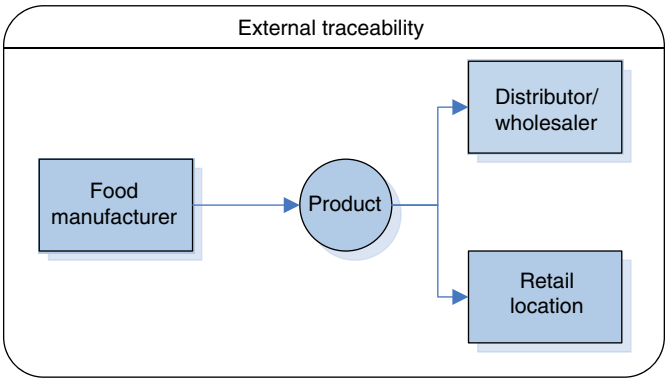

Figure 1 Example of external traceability. A food manufacturer produces a product and tracks the distribution of that product to a distribution and retail location.

remain elusive. Therefore, the hope to eliminate the notions of 'external' and 'internal' traceability in favor of the more comprehensive concept of Critical Tracking Events (CTEs) that are applicable throughout the supply chain while offering greater efficiency as well as data security.

The Old Concept of 'External Traceability'

Transactions between growers, processors, distributors, shippers, brokers, and brand owners (Figure 1) represent external traceability and all segments of the supply chain must participate for such a traceability system to be effective. Missing data slow or stymie investigations. External traceability is largely in practice today throughout the supply chain because companies naturally maintain records of shipments received from suppliers and shipped to customers for the regular business practices of invoicing and payment.

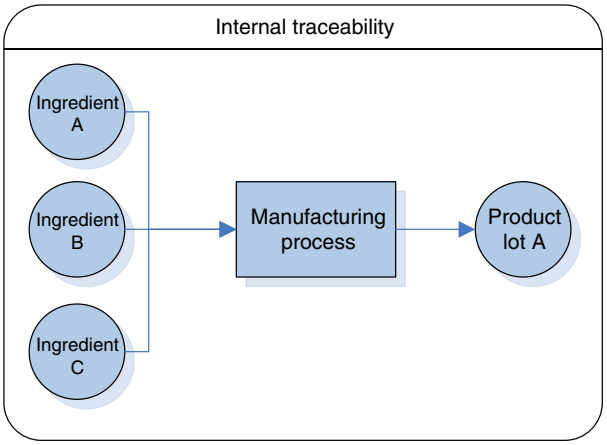

Figure 2 Example of internal traceability. A food manufacturer produces a product from three ingredients. These inputs are recorded and related to Lot A of the finished product.

The Old Concept of 'Internal Traceability'

Internal traceability (Figure 2) requires that food processors or distributors track internal inputs that change the identity or configuration of the product they are selling. For food manufacturing, internal traceability may require that all lot code or batch information for the ingredients (grain, corn syrup, flavorings, vitamins, etc.) that are used be recorded and stored. For a distributor, internal traceability may require that multiple data elements be recorded if cases of product from varying lots are used to create a pallet (or an equivalent logistic unit).

What is sometimes referred to as 'internal traceability' is not actually traceability, but rather good manufacturing practice. There is no doubt that these data are useful to outbreak investigations, but they are not needed in any investigation until they are actually needed by investigators, due to implication of the specific operator in a specific outbreak. In other words, investigators should only need these data from operators implicated as a likely source of contamination. Forcing investigators to dig into these records of each supply chain operator, whether implicated or not, wastes precious time of both investigators and operators, which not only jeopardizes the entire investigation, but also frustrates everyone involved with lots of tedious and expensive work, and relying on these data for routine traceability is unwieldy and unnecessary. Better approaches are needed to more quickly identify the most likely sources of contamination in order to avoid wasting precious time and money of operators who should be excluded from an investigation.

An Example Investigation

Traceability, in order to protect public health, should encompass all aspects of the food system, starting at the point of harvest and continuing to retailers. Animal feed, as well as food packaging, should also be included in a robust food chain traceability system.

Numerous foodborne outbreaks over the past several years have demonstrated the importance and need for rapid traceability of food products sold to consumers. More rapid traceability can aid and clarify foodborne illness investigations by aligning product distribution data with epidemiological exposure data. These investigations could be completed more rapidly and with a greater degree of accuracy if current data

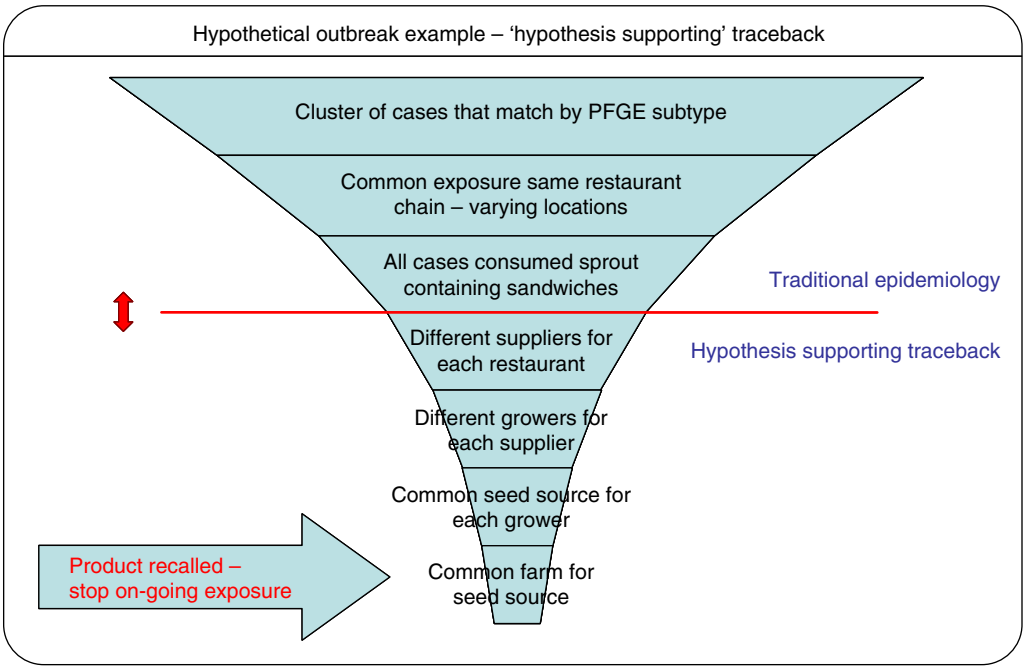

Figure 3 Conceptual diagram of a 'hypothesis supporting' traceback investigation. PFGE, pulse field gel electrophoresis.

requirements and collection practices for food traceability were better defined and aligned across the food supply chain.

Figure 3 shows a cluster of illnesses matching a pulse field gel electrophoresis subtype identified by epidemiologists at a state health department. Owing to the difficulty and cost of traceback investigations, significant clusters of illness must be identified before an investigation commencing. Once the cluster has been identified, epidemiologists interview specific cases and try to determine commonality such as dining at operations of the same restaurant chain. Further investigation finds that all cases consumed some type of sprout-containing sandwich at each restaurant location, but the source of the sprouts remains unclear.

Although the epidemiological investigation may identify a plausible source, the regulatory investigator must trace the likely exposure to a point of convergence or commonality in the supply chain in order to identify the 'source' of the outbreak.

Continuing with the example, once an outbreak vehicle is identified, the epidemiological investigation ends with the possible recommendation that persons not consume sprout-containing sandwiches at these locations. The traceback investigation is an extension of the epidemiological investigation and it serves two purposes:

1. It supports the epidemiological associations by confirming that temporal and physical distribution of suspect products could adequately match the case exposures, and
2. It further characterizes the source of the outbreak, thereby increasing the likelihood of a meaningful intervention to protect public health.

In Figure 3, this concept is demonstrated when the investigation moves from the information generated in the epidemiological interviews to the information collected by a food regulatory agency based on record collection and in-field investigations. An investigation of the invoices and bills-of-lading from each restaurant location where a case of illness was reported shows that each restaurant received their sprouts from a different supplier. Further investigation of the records from the suppliers shows that they received their sprouts from a number of different growers. A review of the grow logs, seed sources, and invoices at each of the sprout grower locations shows that all of the seed in implicated time frame would have come from a single seed-supply company. A review of the lot codes for the implicated seeds shows that a common lot-code of seed was used at each grower in the implicated time frame and further investigation shows that the lot-code corresponds to a single farm that produced all of the questionable seed.

It is not until all of these data are collected and analyzed that a truly meaningful public health intervention, in the form of seed and sprout recalls and a market withdrawal of the implicated lot-code, can be made. As might be imagined, such an investigation is complicated and time- and resource-intensive. Outbreaks often subside before investigators are able to pinpoint a cause resulting in wasted time and effort of both doing the investigating and those being investigated.

Traceforward Investigations

Traceforward, sometime called 'tracking,' is the capability to find a product based on specific criteria while it is handled along each point of the supply chain. This is a critical feature of any traceability system because companies must be able to identify and locate their products within the supply chain in order to withdraw or recall them whenever necessary. Once a food item or ingredient has been associated with illness, improving forward traceability through the channels of

distribution can prevent further consumer exposure and additional cases of illness. Additionally, labeling on consumer packaging for manufactured foods with information containing lot or batch codes will allow consumers to easily identify products in their homes that may be associated with a recall or outbreak.

Limitations of Current Systems, Technology, and Thinking

Improving investigatory efficiency requires knowledge of the process of investigation, supply chain logistics, food handling and production, as well as associated technological developments in these areas. However, recent efforts have focused on testing existing food traceability practices and/or augmenting these practices with not-well-understood emerging technologies such as radio frequency identification (RFID) in the hope that they might offer a 'silver bullet'-style solution. Efforts have also been made to coordinate use of specific data elements throughout the supply chain but with limited success (e.g., Produce Traceability Initiative), because there simply can never be a one-size-fits-all solution for such a large, complex, and dynamic web of supply chains. What is needed is a more general framework that can be applied to a variety of situations. The authors believe that this framework is offered by the concept of 'CTEs.'

One-Forward-One-Back

Currently, food traceability revolves around the concept of OFOB, which is often also referred to as 'one-up and one-down.' This approach is popular because it does not require operators to do anything other than to maintain customary business records that virtually all responsible operators already maintain without the additional consideration of food traceability. The concept of OFOB requires that each operator be able to determine, within a reasonable amount of time and typically within 24 h, the identities and locations of immediate suppliers and customers. Production records, purchase orders, sales orders and invoices, as well as shipping and receiving records substantially satisfy the basic food traceability requirements of OFOB. From the perspective of the operator, OFOB 'works' and requires little if any additional investment other than what might normally enhance business productivity in terms of improving efficiency of data storage and retrieval. Without even considering traceability, responsible operators already maintain a variety of important business process records such as payroll, production, receiving, shipping, sales orders, invoices, purchase orders, inventory, and quality-control data. As mentioned, most of these data are only useful to food outbreak investigators after likely sources of contamination have been identified.

Indeed, OFOB does work, but the problem is that it is slow, inefficient, and often ineffective for investigators, resulting in too many unsolved outbreaks, implication of incorrect products, unnecessary damage to industries and brands, and waste of enormous quantities of otherwise wholesome foods. A better understanding of the investigative and recall processes helps to expose why OFOB is more likely to be incapable of substantially improving food traceability accuracy and speed regardless of capital investments made. The information contained in business process records simply cannot be collated and analyzed quickly enough by investigators to quickly reconstruct the supply chain and identify points of convergence.

The investigative and recall process generally begins with epidemiological evidence of an outbreak. As illnesses are being reported, epidemiologists must wait to identify genetically related 'clusters' of multiple-reported illnesses before commencing the investigation. Once one or more clusters are deemed to be sufficiently promising to pursue, investigators attempt to discover the most likely foods and/or ingredient suspects and their most immediate source (e.g., package, store, restaurant, etc.). Typically, multiple foods and/or ingredients are suspects and multiple simultaneous traceback investigations must be initiated.

For each suspect, investigators seek to learn the immediate source of the suspect product (i.e., one back). Requests for information are made from suppliers in order to identify subsequent suppliers. In this manner, investigators follow the trail backward until the source of the outbreak is identified by multiple traces converging on a particular item and/or location or the trail simply 'goes cold' (Miller, 2012).

Points of convergence provide investigators with the greatest degree of confidence in identifying potential sources of outbreaks. Once one or more points of convergence are identified, sampling and testing may or may not confirm the cause and a decision must be made whether or not to recall suspected product as well as define the scope of the recall. Then the OFOB process works in reverse in order to identify and remove implicated product from the supply chain.

The problem with OFOB is that it is slow and inefficient. OFOB is slow because investigators must work their way backward one supply chain node at a time and each node may use the customary 24 h to provide data that identify the next node in the chain. It is inefficient because investigators must simultaneously pursue suspect foods and ingredients that are not a cause of the problem and this not only wastes precious time for investigators, but it also wastes time of all operators who receive requests for such data. As time is spent, people may continue to consume contaminated food, illnesses mount, and the likelihood of confirming the correct source of the outbreak diminishes.

Anything done under the guise of improving food traceability performance, particularly with respect to government regulation, should have the potential to significantly reduce the time required to identify points of convergence in the supply chain. Doing anything else will not do much to improve food traceability performance but will add substantial costs to operators, which must be passed onto consumers in the form of higher food prices. Imprudent regulations also raise the barrier to entry into commerce, thus depressing innovative start-ups and job creation in the food industry.

Limitations of Lot or Batch Numbers for Traceability

The role of the 'lot number' or 'batch number' serves as a significant example to illustrate the consequences and

challenges of applying production-oriented concepts to food traceability. Most production workers are food safety oriented. When food safety is in question, workers tend to focus on lot/batch numbers in order to understand the scope of the problem because the lot/batch denotes product that was produced or treated under similar conditions using related inputs. Lot numbers are critical when the source of contamination is identified, but because they tend to be operator specific and meaningful only to a given operator within the supply chain, lot numbers are not particularly useful to traceback investigations until a specific operator's facility is implicated. Indeed, each operator has different definitions of lots and batches and food products often become ingredients to other food products making it difficult to recreate paths through the supply chain using lot/batch codes. However, once investigators pinpoint an operator as a likely source of contamination, that operator's specific lot/batch codes as well as all other related information such as payroll (who was working that day), storage room temperatures, cleaning records, etc. all become critically important to investigators. Therefore, although food production and food safety workers often passionately argue for using lot/batch codes as a central component of food traceability, it should now be clear that lot/batch codes are less than ideal for solving the logistic food traceability problem. To be clear, the authors are not arguing for elimination of the use of lot/batch codes for the purposes of production management. They recognize that these data are critically important to food traceability investigations but only when investigations lead to a specific food production operation.

Even if not used as a basis for traceability, lot/batch codes will continue to play a pivotal role in outbreak investigations once points of convergence or the source of tainted food is otherwise identified. Lot/batch codes will serve as the key data element ('KDE') for subsequent trace-forward investigations and recalls. However, it should be clear that this KDE need only exist at the operator in a form convenient to the operator.

Implementation of the CTE framework requires minimal and highly abstracted data (data that are meaningless to observers who are not authorized to access secured, related data) to be collected in a format that can ultimately be accessible electronically. Proprietary production data, such as lot/batch codes, need not be immediately accessible electronically because the goal is to quickly find the source(s) of convergence and/or contamination. Once convergence is identified in the supply chain, thorough investigations will require review of all pertinent documentation in all formats. The goal is to quickly focus the investigation, not to burden every operator with unnecessary data collection and associated restrictions on data formatting.

The notion of unique identification codes has tended to stir up passionate debates and resistance among operators, but this may be due to a lack of understanding how such codes can greatly simplify the traceability process. Unjustified opposition to the use of unique identification codes has led to an unending debate over the 'ideal' universal set of KDEs that might serve the same purpose as unique identification codes (McEntire and Bhatt, 2013). Perhaps the only thing that has been concluded from all of that effort is that there is no universal set of KDEs that will work for all operators in all situations.

Logistic Event-Based Approach to Traceability – Critical Tracking Events

The logistics perspective simplifies the supply chain into a series of events through which food-containing 'units' pass. Units may be shipping containers, pallets, cases, or individual items. Therefore, advancing food traceability requires a decision as to resolution; what is the smallest and most useful unit to be tracked in the supply chain? Because consumers typically purchase individual items in some form of retail setting, it is more likely that the smallest unit received by retailers would be an aggregate of individual units, and the most common aggregation of individual units is the shipping case (typically a corrugated box containing a set number of individual items). Therefore, advancing food traceability will, at least, require some means of uniquely identifying cases. As many individual cases may represent the same lot, there is an associated need for operators to maintain data relationships between production lots and traceability case identifiers.

It follows that advancements in food traceability require collection and maintenance of data and data relationships. This exposes the need for involving expertise in relational data collection, storage, and retrieval for advancing food traceability. Unfortunately, as the topic of food traceability has been viewed primarily as a food safety issue, people with expertise in food safety rather than logistics and distributed relational data have played a primary role in drafting regulatory guidelines that appear to lack sufficient expertise for flexibility, scalability, adaptability, efficiency, and interconnectivity that will be necessary to achieve the goal of food traceability while offering opportunities for adding as yet unforeseen value in the marketplace. Ultimately, a successful global food traceability system will need all of these attributes to grow organically and improve over time.

Current Frameworks and Standards

Worldwide standards and frameworks exist to better facilitate traceability throughout the supply chain. These organizations seek to define data standards so that data are collected in a uniform format and can be more easily shared between trading partners and other entities in the supply chain. In many cases, specific standards have outlived their usefulness and now represent an impediment to advancement. Ideally, enforcement of standards should be avoided wherever possible in order to leave as many avenues for future improvements as possible. Therefore, to the extent possible, conformance with standards should not be required, but rather encouraged and/or provided as examples of modern best practices.

The Critical Tracking Events Framework

These realizations have led to development of a new framework concept for food traceability that offers opportunities to build on past food traceability efforts, tools, and technologies into an easily understandable and universally applicable approach. This framework concept is known as CTEs (Welt and Blanchfield, 2012; McEntire, 2009). The CTE framework

provides a basis for flexibility, scalability, adaptability, efficiency, and interconnectivity with little requirement for enforcing specific standards on any operator. CTE promises to do for food traceability what hazard analysis critical control point (HACCP) has done for food safety. The key concept is that each operator knows their operation best and operators are in the best position to identify those events that are critical to the overall goal of food traceability. The CTE concept simplifies the large, complex, and seemingly intractable problem into a local and familiar series of events that are deemed critical to tracking items through an operation. Each operator properly identifies their own CTEs and commits to collecting a minimum set of event data for each CTE, typically consisting of a three basic data items including unique location/event ID (e.g., Receiving Door #2 at a given physical address), unique item ID, and date/time stamp. Each operator would collect event data from all of their CTEs and store them as they see fit in secure databases that may be accessed for query by properly authorized personnel. This simple structure leads directly to the possibility of authorized investigators being capable of generating reports showing locations, dates, and times, throughout the entire supply chain, of suspect food items and ingredients, virtually instantaneously and with minimal intrusion and bother to operators. When multiple traceback queries expose points of convergence in the supply chain, investigators can then focus their attention on the broader process and handling data of the implicated operator in order to attempt to identify the source of contamination.

As with HACCP, the CTE framework does not prescribe any particular method or technology for doing so. Operators are free to choose the methods and/or technologies that best suit their purposes. The beauty of the CTE framework is that it is simple, flexible, scalable, secure, and efficient and does not require immediate universal participation in order to benefit from the system. As operators adopt the CTE concept into their operations, the food supply chains will become increasingly traceable. Additionally, modern distributed data networks preclude any requirement for pushing or uploading CTE data to any central repository, government, database, or authority. The CTE concept permits operators to maintain ownership and control of their own CTE data. As unique traceability codes can only be linked to proprietary production-related data such a lot/batch codes, CTE offers a level of security through data abstraction. This means that unique traceability codes have no inherent meaning. They simply point to a richer set of meaningful data in properly secured databases. Table 1 depicts the conceptual relationship between HACCP and CTE.

Table 1 Comparison of hazard analysis and critical control points (HACCP) and critical tracking events (CTEs)

HACCP	*CTEs (product tracing)*
Conduct a hazard analysis	Identify products and product inputs to be traced
Identify critical control points	Identify CTEs
Determine critical limits	Determine key data elements
Establish monitoring procedures	Establish data collection procedure
Establish corrective actions	Establish data storage procedures
Establish verification procedures	Conduct mock tracebacks
Ensure recordkeeping	Maintain a written record of the product-tracing plan

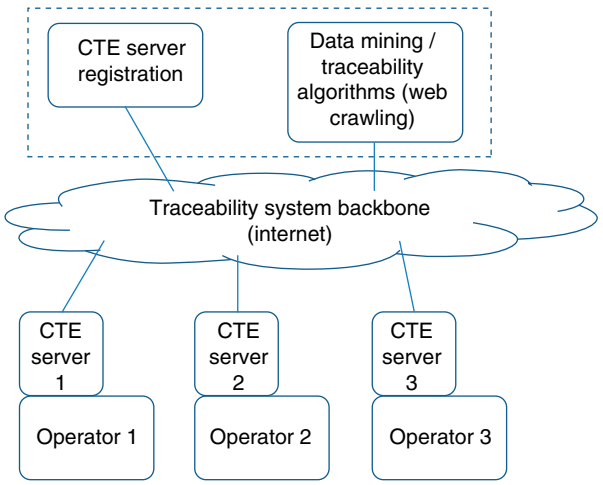

Figure 4 The CTE framework permits operators to control their own data while making them available for rapid traceback investigations without exposing proprietary data.

Data Security

Generally, supply chain participants do not wish to expose proprietary data to competitors and most prefer to not be put in a position that requires trust of government agencies and/or third parties to secure such data on their behalf. It is, therefore, unlikely that the vision of a central data repository controlled and/or accessible by FDA or another government entity, to which all food traceability data must be pushed, represents a sound solution. A similar effort was envisioned in the 2000s by the USDA to create a national database with all farm premise locations and animal movement data to a centralized database to be used in animal disease outbreaks. Resistance from industry and trade associations quickly derailed this effort (Pendell *et al.*, 2010). In contrast, although CTE does not prescribe a particular solution for data handling, the CTE framework invites development of modern, massively distributed, and highly abstracted and secure data-handling methods. These modern approaches to data handling provide for operator ownership and complete control over their own data. Data abstraction provides inherent top-level security in that exposed codes do not expose meaningful information. Ideally, traceability codes should simply point to meaningful data within secured databases that can be physically and logically distributed and only accessible to properly authorized personnel with proper permissions from data owners.

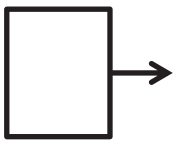
Briefly, an example of a CTE distributed data approach involves collection and storage of CTE data at the physical location/address of the events. Operators would maintain a database on their own site or contract with a third party to host their data in much the same way that many operators contract with third parties to host their web presence or to handle critical and proprietary payroll functions (Figure 4).

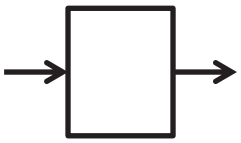
Event data would be stored in an operator-owned and -controlled database which is secure. By securely connecting

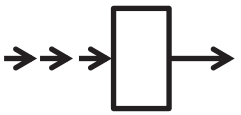
these data servers to the internet/cloud, investigators could use modern and increasingly advanced querying and data-mining tools with appropriate authentication and permissions and determine which events suspect items traversed. In this manner, investigators will be able to rapidly identify paths of different suspect products through the supply chain with minimal interruption to operators. Rapid identification of points of convergence would permit timely and focused investigations as well as targeted recalls resulting in fewer illnesses and deaths, reduced food waste, and less overall damage to industries and brands.

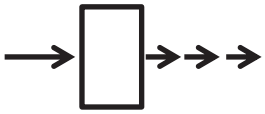
Categorization of Critical Tracking Events

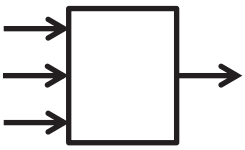
The supply chain can be divided into four categories of CTEs, namely terminal, transfer, aggregation/disaggregation, and commingling (Table 2).

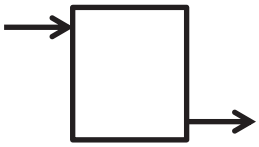












Terminal Critical Tracking Events

By definition, terminal CTEs exist on the boundary of the supply chain. Products enter and exit the traceable supply chain through terminal events. Specific situations always vary and it is the role of the operator to determine how internal linkages are made between CTE data and their actual operation. For example, consider an operation where produce is harvested from a particular field on a particular day. Harvested produce is collected in bulk and delivered by truck to an operation involving cooling, washing, sorting/grading, and packing. To do this, the operator may use the point where packed cases emerge from the operation to initiate supply chain traceability. This terminal event need not be at the field of harvest so long as the operator's records are capable of leading investigators to the source field should that be necessary in the future. The terminal CTE defines entry of this food product into the supply chain. Again, the CTE could be associated with more internal data elements if the operator so chooses such as harvest worker, environmental temperature, sampling results, and/or other relevant production data items. However, for the terminal CTE, the KDEs are simply identification data to define 'what, where, and when.'

Aggregation/Disaggregation Critical Tracking Events

Following the terminal CTE (which in this example occurred at the case level as product sorted and packaged), the

Table 2 Four categories of critical tracking events (CTEs); terminal, transfers, aggregations/disaggregations, and commingling

CTEs category	*Description*	*Diagram of inputs and outputs at event type*
Terminals	1. Creation, origination 2. Disposition	
Transfers	1. Shipping 2. Receiving	
Aggregation/disaggregation	1. Item ↔case 2. Cases ↔ pallet 3. Pallet ↔ container, trunk, etc. 4. Container ↔ ship, rail, etc.	 
Commingling	1. Blend 2. Formulate 3. Bulk commingling 4. Rework	 

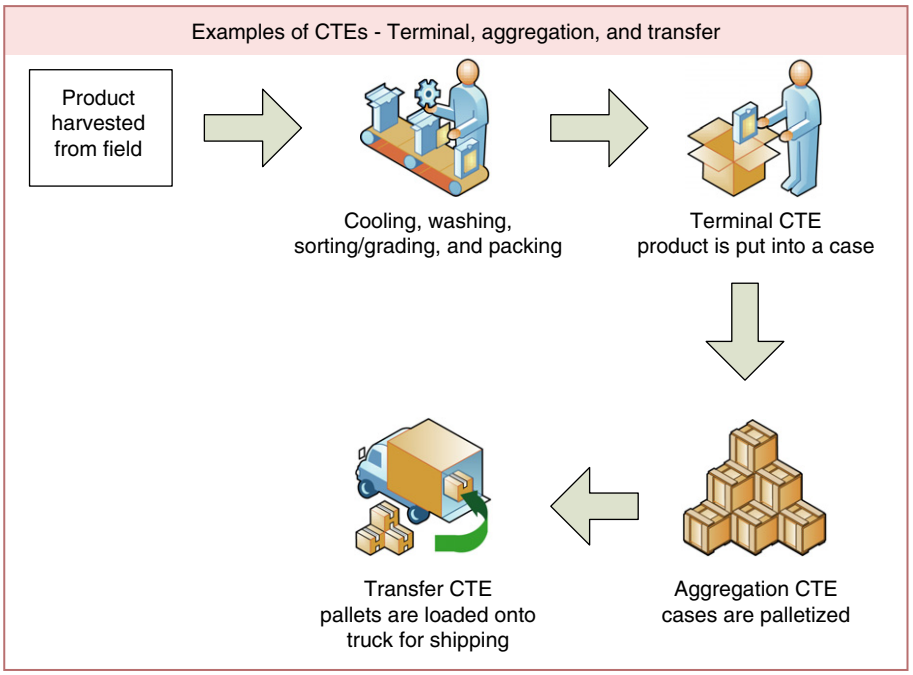


Figure 5 Example of CTEs in a simplified produce-packing facility (terminal, aggregation, and transfer CTEs).

packinghouse has identified an aggregation CTE in their process. As cases of product are palletized, an aggregation CTE exists and captures data identifying which cases comprise an individual pallet.

When pallets are broken down, the process works in reverse in that one incoming object (pallet) results in many outgoing objects (cases).

Transfer Critical Tracking Events

For the hypothetical produce harvester, a transfer (shipping/receiving) CTE is created when pallets of product are loaded onto a truck for shipment.

Commingling Critical Tracking Events

Commingling is usually an irreversible process where items from multiple sources of the same item and/or different items are blended together to create a new product. Comingling CTEs are typically characterized by many inputs and one output (Figure 5).

Lot-Coding Considerations Using Critical Tracking Events

Continuing with the produce-harvesting example, the operator must answer the 'what?' question. In other words, 'what is this item that is being introduced to the supply chain?' First explore why lot numbers are not a good choice for answering this question. The operator is free to define a 'lot' in a manner that makes most sense to the operation. Perhaps a shift's worth of production, a partial shift, one or more bulk truckloads, etc. Whatever the operator uses, it is highly likely that any given lot will be subsequently subdivided down the supply chain and those operators will have their own definitions for their own lots that make sense to their own operations. Clearly, the term 'lot' is more of an idea than a universally defined term. Although this alone should provide a sufficient argument against the choice of lot numbers as the core data for traceability, at least two additional arguments might be made against use of lot numbers. First, lot numbers are currently elusive when dealing with an unpackaged food or an ingredient. Lot codes are often inconsistent and change meaning throughout the supply chain and therefore represent limited utility when conducting a traceback. Lot codes are generally more useful when conducting a recall and therefore targeting specific production units in the supply chain. When the source of an outbreak or point of convergence is identified, investigators and operators need to know the size of the lot or lots associated with the implicated product in order to commence the subsequent investigative process and initiate the recalling of food. Using CTEs, until the source or point of convergence is identified, investigators have no need for every operator's definition of their own lots. They simply need an effective means to find points of convergence. Another issue with using lot numbers is that they tend to unnecessarily expose intelligence about production volumes and inventory turnover to competitors and customers and present food defense risks. This may or may not be deemed important to any given operator, but operators should be free to choose whether or not they wish to expose those data without being forced to do so by regulation. Therefore, although lot numbers currently are critical to the investigative process, lot numbers do not represent an ideal means for tracing items through the supply chain. Implementation of the CTE concept throughout the supply chain will obviate the need for investigators to focus primarily on lot code information as a proxy for internal traceability because case level traceability may be more widely available.

Critical Tracking Event Codes

CTE traceability codes (Table 3 below) answer the 'what?' question and should simply permit unique identification of an item in the supply chain. This means that the code need not provide rich information about the item, but rather the ability to distinguish one item from another in the supply chain. For example, it is now common to use electronic identification to pay tolls on highways. Drivers are issued a device that contains a unique code. The code itself does not contain any descriptive information about the driver or the driver's automobile. Knowledge of the code would not allow someone to know the driver's height, weight, or hair or eye color. The code is simply a number that, when applied to the right database, is able to locate the driver's database record for billing. Although it is more likely that descriptive information about the driver exists in the database, only properly authorized personnel may access it.

The example of automated toll collection applies directly to the CTE framework. The toll collection history shows only the data necessary to identify the item/car and its path in space and time ('What?,' 'Where?,' and 'When?'). For food traceability, this is actually all that is required during the first traceback step of an investigation. For traceability purposes, it does not matter whether the item was cheddar cheese or shredded cheese or even cheese. Only a record of which CTEs handled that item with a particular unique traceability code and when ('What?,' 'Where?,' and 'When?') is needed. It is often forgotten that the operator associated with the terminal creation CTE for any item could, if asked, provide all of the necessary information associated with the creation of the item and its introduction to the supply chain (provided they properly associate these data with the terminal CTE). The purpose of the traceability codes is to efficiently direct investigators to the operator if associated product might be implicated in an outbreak. Therefore, the best code to be used for traceability has at least the following traits:

1. Globally unique.
2. Least amount of data/bits as possible and practical.
3. Simple to print, write, and/or encode.
4. Simple to read.
5. Contains no 'meaningful' information about the product or operator (i.e., does not carry decodable information such as Julian date, etc.)

Technology Considerations and Platforms

There are a variety of coding options available that provide reasonable guarantees of uniqueness. One option that has received considerable attention was developed as a consequence of advances in RFID technology is the electronic product code (EPC). Through standardization efforts, the EPC is widely referred to as a serialized global trade identification number (sGTIN). The GTIN has been in use for a long time and is most recognizable as the Universal Product Code (UPC) printed on most food packages (Figure 6).

As with the lot number, the GTIN or UPC code does not identify a specific item, but rather a type of product in general. The sGTIN is a simple modification that adds a serial number to the GTIN to provide unique identification of items in the supply chain. GTIN codes and therefore sGTIN codes are managed globally through GS1, a non-profit international standards organization, on a subscription basis. Although GS1 is widely recognized and respected, there may be reason for an operator to wish to use another coding system now or in the future. The CTE framework simply requires uniqueness while the code exists within the supply chain. Therefore, the only practical limitation on coding systems is ensuring that others in the supply chain can also read codes. It is worth noting that the GTIN was established before development of modern computing technologies and practices. GTIN and sGTIN codes inherently deliver meaningful data within the code, such as manufacturer identification. Serialized code data may also provide insight into production volumes and rates. Exposing such data may or may not be desirable to operators, especially when exposing such information is not necessary under the CTE food traceability framework. Therefore, the authors recommend that operators consider alternative coding schemes that simply satisfy the basic CTE requirements.

Contrary to an apparently common tendency to seek enforcement of compliance with data standards and structures, readability is the only important requirement for achieving

Figure 6 Universal Product Code (UPC) code including company prefix, item reference number, and mathematically calculated check digit.

Table 3 Examples of traceability codes: The codes are represented by the Unique IDs created for each combination of CTE type, name, and location

Critical tracking events type	*Name*	*Location*	*Unique ID*
Terminal creation	Procedure case packer	Washing/sorting/packaging machine	XYZ123
Aggregation – Palletizing	Produce palletizer	End of conveyor	ABC321
Transfer – Shipping	Shipping dock door 2	Shipping dock door 2	DEF456

CTE-based traceability. Standardized data formats may offer some limited benefits, but as long as trading partners are capable of reading codes of other trading partners, whether similar in structure to their own or not, CTE-based traceability can be accomplished. There is no technical reason that all supply chain participants use similar identifying data types or structures. Modern computer applications are very well suited for generating unique identification codes. Therefore, many readily available options exist for generating unique identification codes under the CTE framework.

With the ability to assign unique identification codes to items in the supply chain, the authors turn their attention to the question 'Where?' and 'When?' Each CTE represents a repetitive event that occurs at a specific location. At worst, the location can be defined by the physical address of the operator. At best, it can be defined by the specific location within the operation where the event takes place, such as a piece of processing equipment or warehouse shelf. The event is often defined by a particular machine that is bolted to the production floor. Extending the prior produce-harvesting example (Figure 5), the terminal creation event might occur on the output side of the cooling/washing/sorting/packing operation where cases emerge on a take-away conveyor before being palletized. The operator could choose to apply preprinted and coded labels (manually or automatically), directly print codes on cases, print and then apply labels to cases, etc. However, if codes are applied, it is possible to uniquely identify the location of the event as well as capture a date–time stamp for each occurrence.

Again, GS1 offers a data standard for uniquely identifying locations known as the global location number; however, any unique identification number chosen to describe the CTE location is sufficient to achieve CTE-based traceability.

As an operator identifies, instruments, and documents CTEs within the operation, it becomes clearer how proprietary data remain secure while meaningless identification codes are used to point to rich sets of data within operators' secure organizations.

For the simple example of the harvest operation (Figure 5), three CTEs are identified, including a terminal CTE (creation), an aggregation CTE (palletization), and a transfer CTE (shipping). The operator's proprietary records would describe these CTEs perhaps as shown in Table 3.

The CTE event record for the terminal creation CTE using unique item code '789' would be as shown in Table 4.

Similarly, the aggregation-palletizing CTE would record '789' being associated with the specific pallet. The shipping CTE would record the pallet being shipped. When the product arrived at the next operator, their receiving CTE would record arrival of the pallet. When the pallet is broken apart, the case identified as '789' would be recorded as being removed from the pallet, etc. There is no need to attempt to predict the path of the item through the supply chain because each operator records CTE data themselves.

Where?	*What?*	*When?*
XYZ123	789	January 31, 2013/13:50:23

Ultimately, consumers might purchase sandwiches made with produce from Case '789.' Other cases from the same production lot would have more likely arrived at many other retailers. Using the unique case identifiers, investigators should be able to query the distributed CTE food traceability system essentially asking, "Which CTEs handled Case '789'?" The few CTEs that actually handled the item could alert operators that an affirmative response to an investigative query must be made. At this point, the operator can provide either a quick "Yes, we handled Case '789'" or a more robust response with all dates, times such as "Yes, we saw the item at (CTE location XYZ123) on (Date/Time)."

The dataset compiled from all CTEs will provide a relatively immediate physical and temporal mapping of the item through the supply chain allowing investigators to quickly visualize the path and timing of multiple suspect items through the supply chain. In many situations, the CTE framework is even capable of jumping over missing nodes, which means that the traceability system will be immediately useful and improve over time as individual operators come online with their CTE data. The CTE framework is capable of satisfying the objective to quickly focus investigator attention on points of convergence, rather than working backward, serially through the cumbersome OFOB process with associated delays at each stop (Figure 7).

Modern interconnectivity of computer networks via the Internet as well as cloud-based storage and computing permit relational databases to exist virtually anywhere. Availability of this highly distributed global data infrastructure obviates the notion of a large central food traceability database. Small-scale operators could still capture these data by hand, if need be, or by the ubiquitous smart phone with appropriate applications.

The CTE food traceability framework fits well with the modern notion of highly distributed data while promoting additional benefits of operators maintaining ownership and control of their data as well as the associated data security that ownership and control affords.

Distributed versus Centralized Data

Although the CTE framework does not necessarily prescribe use of distributed data versus centralized data, it is easy to recognize the benefits of the distributed model over a centralized model. A centralized model requires that all supply chain participants conform to the central data model as well as central interface protocols. Operators would need to push data to the central database in a timely manner. As all operators would be expected to interact with the central database, necessary changes over time would be extremely difficult to implement. Therefore, central databases tend to be inflexible and not easily scalable and therefore become quickly obsolete. However, the distributed model permits operators to maintain ownership and control of their own data. Simple interfaces permit investigators to make infrequent queries of data and operators are capable of controlling the scope and manner of responses. Operators maintain and upgrade their systems as appropriate without interfering with the rest of the supply chain in much the same

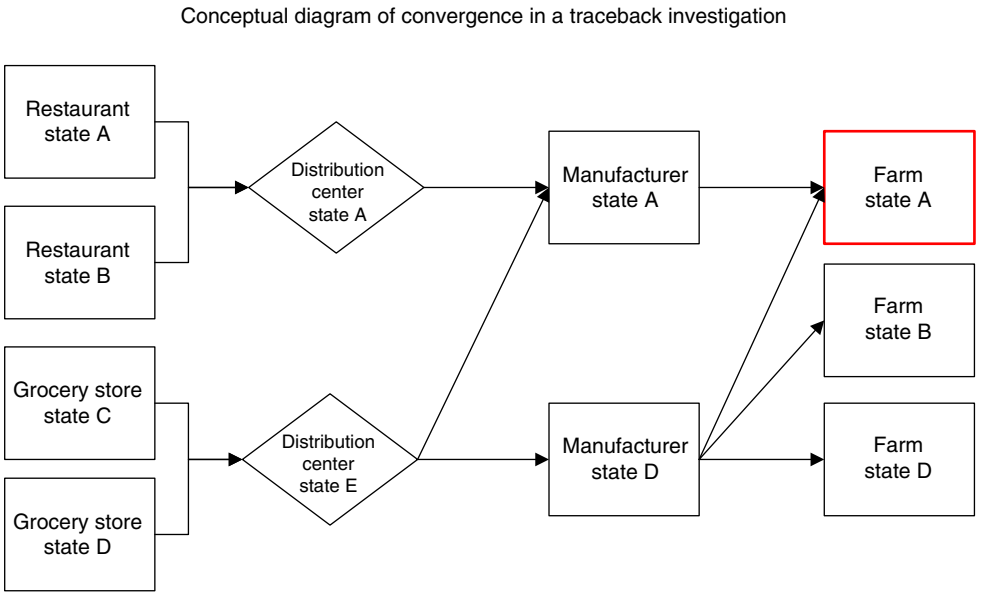

Figure 7 Simple conceptual diagram of traceback investigation. In this investigation, product is traced back to a point of convergence at Farm A.

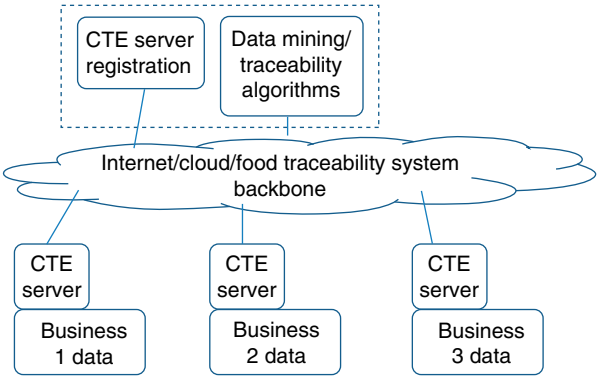

Figure 8 Conceptual diagram of CTE Traceability backbone. CTEs can be identified by leveraging cloud-based search algorithms and distributed databases. Unique traceability IDs would be identified by leveraging cloud-based search algorithms and distributed databases. Convergence in the supply chain is quickly identified.

way that companies can upgrade their own websites without interfering with the rest of the Internet. In contrast to the central database model, the distributed data model is flexible and scalable. Leveraging the modern distributed data infrastructure will permit rapid and independent expansion and utilization of CTE-based food traceability (Figure 8).

Conclusion

Past outbreaks have demonstrated the need for more rapid and accurate food traceability. Using existing standards and technologies, and adopting the CTE concept of traceability, would allow industry and regulators to intervene in outbreaks and prevent additional cases of foodborne illness. CTE allows for more targeted food recalls, potentially limiting the amount of unaffected food that would need to be recalled and destroyed. In turn, better traceability based on the CTE framework will result in increased public confidence in the food supply because implicated or adulterated food would be rapidly identified and removed from sale.

Glossary

Actuarially fair Means that premiums on policies equal the expected payments from the policy.
Adverse selection Occurs because of asymmetric information. After insurance premiums are set, potential insurance purchases evaluate premiums. Individuals with more risk will purchase crop insurance and those with less risk will not purchase insurance.
Moral hazard Occurs after an insurance policy is purchased when purchasers take on more risk with the policy than they would without the policy.
Multiperil Crop insurance covers all yield losses that are naturally occurring.
Premium The costs of insurance.

Introduction

Crop insurance is a contractual agreement between a farmer and an insurer under which the farmer pays a premium to the insurer and the insurer agrees to make insurance payments contingent on events occurring in the future that trigger losses as defined in the crop insurance contract. Crop insurance payments are intended to reduce risk by making payments when a farm is under financial stress. Under better than average outcomes, a farmer pays a premium but does not receive a payment, so the intended net effect of insurance is to reduce the range of possible outcomes that farmers can experience.

Most insurance markets are regulated to assure that insurance companies can make the insurance payments stipulated in insurance contracts. Conceivably, this regulatory function could be the only governmental involvement in crop insurance. In the United States, however, the federal government is much more heavily involved in crop insurance. The federal government determines the specifications of federal crop insurance contracts that are sold to farmers, sets premiums that farmers pay on crop insurance policies, subsidizes the costs of premiums and program delivery, and acts as a reinsurer to crop insurance companies offering crop insurance contracts. It is thus important to understand the role of the federal government in crop insurance markets and how crop insurance differs from other more common forms of insurance. Although each country is unique, many countries are involved in crop insurance and face many of the same issues as in the United States, as noted in the final section of this article.

In the materials that follow, features of the crop insurance market are delineated first by types of crop insurance products available to farmers. Then the history of the involvement of government in crop insurance is discussed, with particular emphasis given to increases in subsidies that have occurred through time. Finally, major issues that have caused difficulties and concerns in crop insurance delivery are outlined and described, along with implications for performance of crop insurance.

Types of Crop Insurance

The various crop insurance products are described roughly in their order of introduction into the US market, progressing from single-peril insurance to multiperil insurance, and then to index insurance. Within multiperil insurance there are two major types depending on whether the yield or revenue associated with the crop is insured. Within the division of revenue insurance, there is a further distinction based on the possibility that the insured amount or guarantee value can increase if prices increase. Finally, index insurance is described with the major types being area insurance plans or group plans and weather event insurance.

Single-peril insurance products provide insurance against a specific named peril, such as hail or wind snap. Hail is by far the most widely used single-peril crop insurance. Hail insurance makes payments when hail occurs and causes sufficient damage to result in an insurance claim. The judgment of damage is made by an insurance adjuster who inspects the affected crop and generally indicates that yields are expected to be reduced by a specific percentage (e.g., the hail event caused a reduction in yield of 30%). After subtracting the deductible, a claim is paid on the basis of a dollar value of protection set in the crop insurance policy. Other than through regulatory oversight, hail insurance policies are not part of a government program and are not federally subsidized, nor reinsured. Hail insurance policies are offered through private companies, and gains or losses are accrued to the private entities backing the insurance. Aiding the development of this private market is the fact that hail events tend to impact small geographical areas with little correlations across areas. These types of losses allow crop insurance companies to diversify risks.

In contrast to single-peril insurance, multiperil yield insurance provides payments for any yield loss resulting from natural causes. Because yield insurance protects against all naturally occurring causes of loss, yield insurance provides superior risk protection to single-peril insurances. Yield insurance contracts are typically implemented by first determining a guaranteed yield. The guaranteed yield is, in turn, determined as the product of an expected yield and a coverage level. The expected yield typically is based on historical yields, sometimes adjusted to reflect changes in farming technologies. The coverage level is a percentage of the expected value, usually restricted to be less than one so as to provide a deductible. Typical coverage levels ranges from 50% to 85%. Payments are then made if the actual yield experienced is less than the guaranteed yield. To illustrate, suppose a farmer with an

expected yield of 160 bushels per acre elects a 75% coverage level. The guaranteed yield is 120 bushels per acre (160×0.75). If actual yield falls below 120 bushels per acre, insurance payments will occur. Payments typically equal the yield shortfall times the indemnified price per bushel shortfall. The price is determined before the realization of yield. In the United States, the federal policy proving yield insurance is called yield protection (YP).

Revenue insurance provides protection against losses of expected revenue. Typically, expected revenue is measured through the uses of prices based on futures contracts, which serve as a measure of the price expected at a future date. A projected price based on futures prices is set before planting and is used to establish the revenue guarantee. A harvest price is determined near the typical time of harvest and is then used to determine available revenue. This revenue is then compared with the revenue guarantee to determine whether an insurance payment will occur. To illustrate, suppose a farmer has a revenue protection policy with an expected yield of 160 bushels per acre and a projected price of US$6.00 determined in this case as the average futures price for the upcoming December corn futures price during the month of February. Given a 75% coverage level, the revenue product will have a US$720 (160 expected yield $\times$ US$6.00 projected price $\times$ 0.75 coverage level). At harvest, actual revenue is measured as actual yield times harvest price. In this case, suppose the farmer had a 100 bushel yield and the harvest price is determined to be US $7.00, yielding revenue of US$700. A payment is made equal to the difference between the revenue guaranteed and actual revenue, or US$20 (US$720 revenue guarantee – US$700 actual revenue). In the United States, the federal policy that provides protection against revenue losses is termed revenue protection with harvest price exclusion (RP-HPE).

Revenue insurance is also available under which the guaranteed revenue is based on the higher of the projected or harvest prices, known as revenue protection (RP). In essence, the guaranteed revenue under RP resets using the harvest price if the harvest price is above the projected price. RP insurance will make the same insurance payment as RP-HPE if the harvest price is below the projected price. However, when the harvest price is above the projected price, RP insurance will pay more than RP-HPE. Continuing with the example above, a farmer with a 160 bushel expected yield, a US$6.00 projected price, a US$7.00 harvest price, and a 100 bushel yield would have revenue guaranteed at US$7.00 $\times$ 160 $\times$ 75% or US$840. RP insurance would make a payment of US$140, or US$120 more than RP-HPE because the indemnity price increased to the larger of harvest or projected price.

The Federal Crop Insurance Corporation (FCIC) offers all three types of farm-level crop insurance in most counties with significant crop production, across a wide range of coverage options. In locations where all three of these multiperil products are offered for a single crop, RP tends to be the most popular. For example, 73% of the corn acres were insured with RP in 2012, 3% with RP-HPE, and 10% with YP (Risk Management Agency, 2012). Revenue policies generally have been shown to provide superior risk protection compared with yield policies, likely accounting for the higher use of revenue insurances. The guarantee increase allowed in RP is useful for farmers who hedge compared with the use of YP or RP-HPE. In cases of yield declines, which are often widespread, prices often increase, leading to hedging losses and the guarantee increase provision of RP is intended to offset these losses and allows farmers to make pricing decisions before harvest if conditions warrant.

In contrast to multiperil products, index insurance products do not insure a particular event on a farm, but rather they provide payments when an index falls below a threshold. For index insurance to provide risk protection, the index has to be highly correlated to losses on a farm. Index insurance products potentially have a number of advantages over multiple peril crop insurance products. First, index insurance does not require measurement of yields from an individual farm, the determination of which can be a costly error-prone activity. Moreover, index insurance reduces the possibilities of moral hazard and fraud, because a farmer cannot influence the value of the index.

Within the United States, the most prevalent type of index insurance is provided in the form of area insurance or group plans. These plans typically make payments based on county yield or revenue. Group risk plan (GRP) is a county-level insurance that makes payments when a county's yield falls below a guaranteed level, usually determined as a coverage election times an average or expected yield. Group risk income plan (GRIP) is a county-level insurance product that makes payments when county revenues fall below a county revenue guarantee. GRP is similar to YP based on a county yield and GRIP is similar in concept to a county-level RP policy. Both GRP and GRIP are federally subsidized products. Use of these products has been confined mainly to the Midwest, and in the Midwest they represent a low portion of policies. In Illinois, for example, GRP and GRIP accounted for 0.4% and 5.3%, respectively, of corn acres insured in 2012 (Risk Management Agency, 2012).

Weather indexes are another form of index insurances that make payments based on measures of weather events, such as temperature or rainfall at specific locations, like weather reporting stations. Various forms of weather insurances exist, including policies that make payments when: (1) rainfall is below a specified level during a specified time interval, (2) some combination of low rainfall and high temperatures occur in a specified range, and (3) 'early' frost occurs. Rating of index products is relatively straightforward as plentiful historical data exist from which the likelihood and severity of potential payments can be assessed. Typically, weather insurance products are free from moral hazard and adverse selection concerns, as the purchaser cannot affect the index with their own behavior. However, developing weather insurance policies that follow yields closely enough to substitute for direct farm-level insurance is still problematic in many cases. Weather insurance is currently offered privately in the United States. Weather insurance products have been attempted in developing countries in efforts to provide basic levels of production insurance, often before the development of the infrastructure and data needed to support specific farm-level contracts.

History of Involvement of Federal Government in Multiperil Crop Insurance

Several attempts to offer multiperil crop insurance were made by private crop insurance companies in early parts of the

twentieth century. In 1917, for example, private insurers offered policies in North Dakota, South Dakota, and Montana, but the companies suffered large losses due to a drought and did not continue offering insurance (Valgren, 1922). Other companies offering multiperil insurance policies were also not successful (Gardner and Kramer, 1986). Partially explaining these failures is the correlated nature of crop insurance losses, making it difficult for a company solely dependent on crop insurance to diversify risks from crop insurance policies. A similar situation exists in other markets where there is government participation, including flood insurance and certain forms of disaster insurance where relatedness of loss experience renders private insurance difficult to offer.

The 1930s saw several major droughts across large portions of the Midwest, perhaps providing impetus for governmental involvement in crop insurance. Federal involvement in crop insurance began with the passage of the Crop Insurance Act of 1934. Soon thereafter, the FCIC was formed to act as fiduciary entity for crop insurance and crop insurance policies were offered to farmers through governmental agencies. The goal when setting premiums was to determine actuarially fair premiums such that premiums equaled the expected payments from crop insurance. In principle, the government could act as a risk-neutral agency to facilitate the formation of a mutual insurance fund that paid out losses from broadly distributed premiums that equaled each other over time. Initially, farmers paid the entire premium for policies, and the delivery of crop insurance was subsidized. However, the early history of crop insurance can be characterized as having poor actuarial performance, with actual indemnities paid out of the crop insurance programs exceeding premiums paid in. Various attempts were then made at improving rate setting, meeting with some success during the 1950s. However, participation in crop insurance remained low and was concentrated in areas where farming risks were highest.

In the 1970s, the US Congress passed legislation that created standing disaster assistance programs (Gardner and Kramer, 1986). These programs were popular with farmers, as farmers did not have to pay to participate in the programs. However, the existence of both disaster assistance and federally sponsored crop insurance raised a number of issues. A disaster assistance program provided much the same protection as crop insurance, hence there was some concern that disaster assistance would substitute for or crowd out crop insurance. The policy position that emerged was that if participation in crop insurance could be induced to occur at high levels, disaster assistance programs could be replaced by crop insurance, which has more desirable distributional features and better aligns risk reduction with actual needs.

Congress then passed the Federal Crop Insurance Act of 1980, which replaced the standing disaster assistance programs with subsidized crop insurance (Glauber, 2004). A goal of the subsidy structure was to induce participation of at least 50% of eligible acres through the payment of a portion of the premium in the form of risk subsidies. As a result, farmers pay only a portion of the total premium, and the remainder is paid by the federal government. Moreover, the delivery of crop insurance was transferred to private companies, with the hope that profit incentives would encourage private companies to aggressively sell insurance. In addition to selling and servicing crop insurance products, the private companies participate in a portion of the underwriting gain or losses associated with the policies. However, even with subsidized insurance and private company delivery, participation in crop insurance remained low through much of the 1980s. When a widespread drought hit the Midwest in 1988, only 25% of eligible acres were insured (Chite, 1988). Low participation, along with political pressure, led to the passage of ad hoc disaster assistance programs again in both 1987 and 1988.

Efforts continued to encourage participation in crop insurance. Congress passed the Federal Crop Insurance Act of 1994, which increased premium subsidies (Glauber, 2004). During the 1990s, revenue and area insurance products were introduced. Before this point, all federal products had been yield insurance products. Revenue insurance proved to be popular and through time became the dominant share of federal policies. Congress increased premium subsidy rates with passage of the Agricultural Risk Protection Act of 2000 (Glauber, 2004). Finally, the 2008 farm bill also increased premium subsidies for enterprise units, a particular manner of insuring that combines all acres in one crop in one insurable unit to encourage insurance in a form more related to actual farm operation revenue needs.

These efforts have resulted in dramatically increased usage of crop insurance. In 1991, only 101 million acres were insured (see **Table 1**). Since 1990, acres insured have increased in most of the years, reaching 282 million acres in 2012. Total premiums paid into the program have also increased from US $836 million in 1990 to more than US$11 billion in 2012 (see **Table 1**). At the same time that total premiums have increased,

Table 1 Acres insured, total premium paid, and precent of premium subsidized, United States, 1990–2012

Year	*Net acres insured*	*Total premiums*	*Premium subsidized (%)*

the federal government's share of total premiums has increased as well. In 1990, 26% of the total premiums were paid by the federal government. In 2012, 63% were paid by the federal government (see Table 1).

The current size of the crop insurance program may have accomplished a major policy goal: replacing disaster assistance programs with crop insurance. Since passage of the Federal Crop Insurance Act of 1980 that eliminated the standing disaster assistance program, Congress has implemented ad hoc disaster assistance programs throughout the 1980s, 1990s, and 2000s. In 2012, however, there was major drought that impacted much of the Midwest and Great Plains, yet no ad hoc disaster assistance program was passed. A major reason given for no disaster assistance program was the size and coverage of the crop insurance program.

Structure of the US Multiperil Crop Insurance Industry

Participants in the crop insurance channel can be delineated into the following five primary groups: farmers, crop insurance agents, crop insurance companies, reinsurance companies, and the federal government (see Figure 1).

Farmers and share-rent landowners first purchase crop insurance. As indicated earlier, farmers pay a portion of the premium associated with crop insurance and receive indemnity payments when insurable losses occur. Crop insurance agents provide information to farmers, help to make product and coverage decisions, and service the policies they sell. Servicing activities include compiling of yield histories needed for the crop insurance policies, collecting acreage information from the farmer, and managing processes associated with getting insurance in place. Insurance indemnity claims are initiated by farmers through their crop insurance agents, although the claim adjustment process is handled by adjusters who are by regulation independent of the agents. Some crop insurance agents are employed by a crop insurance company, whereas many others act as independent agents who sell polices through more than one company.

Crop insurance companies own and service the crop insurance policies and interact with The Risk Management Agency (RMA) in initiating policy coverage and maintaining appropriate records. Crop insurance companies, in turn, receive premiums associated with policies and are responsible for managing the claims adjustment process. In addition, crop insurance companies are subject to underwriting gains and losses associated with crop insurance policies; however, crop insurance companies do not bear all the risks associated with the polices. Much of the risk is borne by the federal government, and private agreements with reinsurance companies also are used by the crop insurance companies to manage risk.

The federal government is heavily involved in the US crop insurance industry on almost every level. Day-to-day management of crop insurance programs and provisions is provided through the RMA, an agency of the US Department of Agriculture. RMA determines the types of polices that will be offered with subsidies from the US government and develops the ratings structures underlying each policy. RMA maintains all data associated with policies and provisions and losses and yield records, across all companies. All companies must offer the same basic policy at the same costs. Thus, for a farmer, the price and terms of a federally subsidized multiperil policy will not vary with the crop insurance company it is purchased from, nor by the crop insurance agent from whom it is purchased.

Reinsurance of crop insurance policies is also accomplished through the FCIC, a wholly owned government corporation. The sharing of underwriting gains and losses is detailed in a loss-sharing arrangement called the Standard Reinsurance Agreement (SRA), in which all crop insurance companies must participate in order to sell crop insurance. All companies are subject to identical term, and hence the 'Standard' label in the SRA. The SRA determines how gains and losses are shared between the federal government and crop insurance

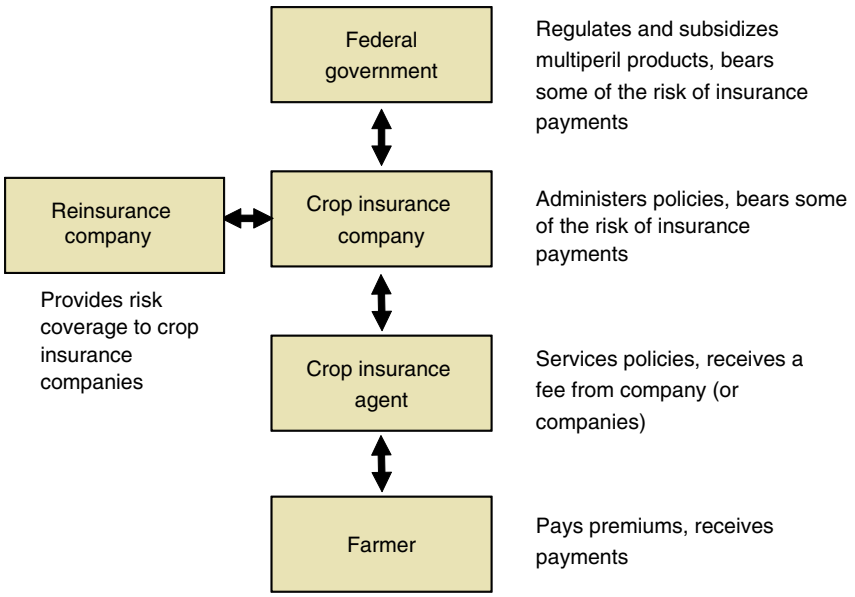

Figure 1 Participants in federal crop insurance.

companies and is periodically renegotiated to maintain performance targets through time. The negotiations around the SRA can be very controversial, as crop insurance companies and the federal government are often at direct odds about the terms of the agreement. Crop insurance companies prefer to retain a higher share of the gains and a lower share of losses, whereas the federal government wants to provide incentives for greatest coverage at lowest net cost. As policy terms and premium determination are set outside a company's control, the terms of the SRA have a large impact on the ultimate financial performance of crop insurance for companies.

Under the terms of the SRA, two funds of policies exist in each state into which each policy may be committed. These are termed (1) assigned risk fund and (2) commercial fund (Risk Management Agency, 2013b). Within specified limits, a crop insurance company must place each policy into either an assigned risk or a commercial fund before determining the loss experience of the policy. Risk sharing differs dramatically across these pools with the ability to retain exposure to policy risk greater within the commercial fund.

For polices placed in the assigned risk fund, the companies cede 80% of the premiums to the federal government. On this ceded premium, the crop insurance company does not receive any gains or losses regardless of the outcome of the underlying policy. On the 20% of retained premium, gains and losses are shared on the basis of a prescribed schedule, with the majority share accruing to the FCIC. To illustrate, suppose that the loss ratio, or indemnity payments divided by premiums, equaled 1.5 at a state level. In this case, losses are 50% greater than premium, and for each dollar of premium, an additional US $0.50 has to be paid, resulting in a loss of equal magnitude. Under the Assigned Risk fund, at this level of loss ratio, the company will have a US$0.04 loss, whereas the FCIC will bear US$0.46 of the loss. As shown in Table 2, the losses increase as loss ratios increase, but not proportionately with loss levels. The company's losses go up with loss ratio to US$0.08 for a 2.5 loss ratio, US$0.11 for a 3.5 loss ratio, US$0.14 for a 4.5 loss ratio, and losses are then capped at US$0.15 for a 5.5 and higher loss ratios.

For policies placed in the commercial fund, the company can retain between 35% and 100% of the total premium in 5% increments. The amount of premium to retain is a company's decision. In the commercial fund, a company bears more of the risk associated with losses. For example, if the loss ratio were 1.5, the company has US$.30 of loss per US$1 of retained premium and the FCIC has US$0.20, if in the commercial fund in Group 1 states (Illinois, Indiana, Iowa, Minnesota, and Nebraska) compared with US$0.04 for the assigned risk fund (see Table 2). If it were in Group 2 or other states, the shares are reversed and the company would lose US$0.20, whereas the government would pay the excess US$0.30. As loss rates increase, the losses borne by the company increase, but the government's share increases faster with maximum losses capped at US$0.88 in the commercial fund in Group 1 states and at US$0.61 in Group 2 states. If there are gains instead, the SRA also determines the split in the excess premium. For example, if the loss ratio is 0.65, then there is a US$0.35 gain per dollar of premium. Under the SRA, the company would receive 26.25 cents and the government would receive 8.75 cents if in the Commercial fund in Group 1 states. In the Assigned Risk fund, the company would receive only 7.89 cents instead and the government would retain the remainder of the gain. The full schedule of losses and gains is prescribed in the SRA and thus a reason that the SRA is so vigorously negotiated.

Intent of the differential loss sharing schedules is to incent crop insurance companies to identify and place their riskier polices in the assigned risk fund. This strategic placement of policies will tend to cause the crop insurance company to have a lower proportion of losses and a higher proportion of gains (Coble *et al.*, 2007) than random assignment or if there were only one average schedule. As discussed in the following section, the fund allocation decisions are also an important determinant of the effective crop insurance subsidy.

Subsidies for US Multiperil Crop Insurance Policies

There are three types of subsidies involved in the US multiperil insurance market: (1) risk, (2) administrative and operating subsidies, and (3) shared underwriting losses.

Risk subsidies directly reduce the farmers' costs of purchasing crop insurance. When setting rates, RMA attempts to determine total premiums so that total premiums roughly equal expected payments from crop insurance policies, thus resulting in actuarially fair premiums, on average. Because

farmers have private information and can likely assess their own risks to determine whether they are more or less risky than average, if all policies were sold at the actuarially fair value, disproportionate participation would be expected by riskier farmers. Partly in response to the difficulty in developing perfectly accurate individual rates, the risk subsidy encourages participation by reducing the costs paid directly by the farmers through these risk subsidies. The percentage of the total premium that is subsidized is set in legislation by Congress. Table 3 shows the current subsidy levels for multiperil products, delineated by type of unit and coverage level. The major determinations are whether the insured unit is an enterprise unit or not. Enterprise units refer to all of one crop in a county and require certain other restrictions to be met before this unit can be used. Alternatively, the crop might be insured in basic or optional units. A basic unit is all of one crop in a county under the same ownership structure. One basic unit exists for all owned and cash-rented farmland, with additional units for each share-rent landlord and by each fraction at risk. Optional units divide basic units based on township sections.

Table 3 Risk subsidies on multiperil insurances

Coverage level (%)	*Unit*	
	Basic optional	*Enterprise (%)*
	Total premiums (%)	
50	67	80
55	64	80
60	64	80
65	59	80
70	59	80
75	55	77
80	48	68
85	38	53

As shown in Table 3, risk subsidies range from 67% of total premium at a 50% coverage level down to 38% at an 85% coverage level. This schedule was set by the Agricultural Risk Protection Act of 2000 and will continue until Congress again modifies subsidies. Enterprise subsidies are higher, ranging from 80% of total premium at a 50% coverage level down to 35% at an 85% coverage level. Before 2008, enterprise units had the same subsidy levels as basic and optional units. The 2008 farm bill included increases in the subsidy rates for enterprise units to encourage aggregated coverage. The intent of the differing subsidy rates, to some degree, is to provide a similar dollar-valued subsidy per acre across all options, with lower subsidy rates against higher valued insurance and vice versa. Both dollar levels and percentages of premium paid in the form of risk subsidies have been increasing over time. For the 2003 cropping year, risk subsidies were US$2 billion. For the 2012 cropping year, risk subsidies were estimated at US $6.9 billion in the United States. These subsidies were larger than the remaining subsidies.

The second type of subsidy is administrative and operating (A&O) expense subsidies. As total premiums do not include cover costs of delivery and total premium, A&O subsidies are designed to provide crop insurance companies funds needed for delivery of the product. A&O subsidies are stated as a percentage of total premiums. Percentages are set within the SRA and vary somewhat with product. The A&O subsidy on most insurance products is 18.5% of net booked premium. For the 2012 cropping year, A&O subsidies are estimated to be approximately US$1.4 billion.

Underwriting subsidies potentially occur when total premiums are greater than total indemnity payments. The SRA determines the relative shares of the gains or losses between the federal government and crop insurance companies. Table 4 shows historical loss experience to federal crop insurance in the United States from 2002 to 2012. The table shows gross premium, which includes farmer-paid

Table 4 Premiums, indemnities, and gains (losses) from Federal Crop Insurance

premiums and risk subsidies. Gross indemnities are subtracted from gross premium to arrive at gross underwriting gains. As can be seen in Table 4, there were gross underwriting gains in all but two years wherein losses were US$1.1 billion in 2002 and losses were US$6.2 billion in 2012. Unprecedented losses in 2012 resulted from a major drought that impacted the Midwest and Great Plains. Over the 11-year period, underwriting gains totaled US$9.1 billion. As a result of the reinsurance agreement, insurance companies have received a larger portion of gains than the federal government. For the entire 11-year period, insurance companies have US$9.9 billion of gain, whereas the FCIC experienced a US$.9 billion loss, providing additional profits to crop insurance companies. Over this time period, crop insurance companies have received an average of US$830 million per year in underwriting gains.

Issues Associated with Crop Insurance

Crop insurance has all the problems associated with any other form of privately offered insurance: ratings difficulties, adverse selection, and moral hazard. As crop insurance is also publically subsidized, it faces policies concerns, including the perennial question of why to subsidize crop insurance in the first place. The following four subsections cover issues associated with crop insurance beginning with ratings issues and moving to more public policy concerns. This progression of issues is not without overlap, as many of the issues are intertwined with one another.

Rating Difficulties and Adverse Selection

Determining the proper rates and premiums for multiperil crop insurance has proven to be a challenge, as evidenced by the poor actuarial performance of crop insurance during much of the twentieth century. Inherent within this difficulty is deriving loss exposure measures that accurately reflect risks for policies under differing productivities and locations. The RMA uses a loss cost approach for determining yield rates, which relies on previous experience from crop insurance policies to determine rates for current policies. Typically, experience from a county is aggregated to arrive at rates for county. This approach has some desirable characteristics but also faces two basic problems: first, the loss cost approach is based on the ability for historic loss rates to accurately proxy future loss experiences. In agriculture, technologies are changing continually, causing yields from farms to generally increase and to change relative to weather and input decisions. Hence, previous loss experience may not totally capture yield variability in the future (Skees and Reed, 1986). Second, land quality varies considerably even within county. Hence, determining rates for a diversity of farmland that exists may be problematic, if not fully reflected in historic yields within a policy record.

These difficulties in ratemaking can lead to adverse selection (Skees and Reed, 1986). Adverse selection occurs when the individuals being insured know more about their risks than the entity setting the rates. Those individuals who know that they are more risky will be more likely to purchase crop insurance than those who know that they have less risk. Adverse selection results in a group of policies that are more risky than reflected in the ratings procedure. Adverse selection likely contributes to poor actuarial performance of multiperil crop insurance but likely more so in the past when participation rates were much lower. Research suggests that rating methodologies have resulted in unequal actuarial performance, with relatively less risky crops and regions having lower losses than implied by the rates (Woodard *et al.*, 2012).

Responses to adverse selection are continuously being undertaken to improve rate making and design-specific risk indicators. Adverse selection also provides impetus for area and other index insurance products, as these are typically easier to rate accurately and face less adverse selection issues (Miranda, 1991). Area insurance products, however, typically do not provide as much risk protection as farm-level polices, as county yields are not perfectly correlated with farm yields.

Systemic Risk

Insurance markets work best when losses across policies are independent and uncorrelated in space or time. Uncorrelated losses allow crop insurance companies to diversify risks and increase the predictability of losses within a time period. Insurance payments become more variable and extreme across time with more highly correlated insurance payments. Correlated losses also result in the need for crop insurance companies to hold more capital to cover potential crop insurance payments. In extreme cases, highly correlated losses can result in the financial failure of an insurance company even if policy premiums are set properly because capital did not exist to cover intermediately large losses.

Crop insurance losses are positively correlated across locations in a given crop year because weather is highly influential on loss experience and because revenue insurance will all be impacted by the same price changes. When severe droughts occur, as happened in the Midwest in 1988 and 2012, crop insurance payments will be large and underwriting losses will occur.

The nature of the systemic risk in agricultural production has been given as one reason for federal involvement in crop insurance. The federal government can act as a reinsurer against the systemic risk that is destabilizing to the private crop insurance companies and not face the same liquidity or capital constraints that individual companies might. Reinsurance through the SRA is one way of providing this protection. Other methods have been proposed, including the use of area yield plans to backstop crop insurance companies (Miranda and Glauber, 1997). In this case, the federal government provides subsidies and payments on area yield insurance, with the remaining farm losses not covered by area insurance to be less positively correlated and more manageable from a private company perspective.

Crop Insurance Impacts on Farmer's Decisions: Moral Hazard, Input Use, and Acreage Decisions

Purchasing crop insurance may result in impacts on other farmer's decisions, with those changes sometimes undesirable, or having effects that are specific to individual interests. Moral hazard is a prime concern within crop insurance, as moral

hazard occurs when a farmer takes more risk in the presence of crop insurance than would be taken without crop insurance. A farmer would take these risks because crop insurance may partially or totally offset losses from adverse events, thereby reducing losses from the risky activity while potential profits still remain. This additional risk taking can cause loss experience to be larger than anticipated for when crop insurance rates were determined. One way of countering moral hazard is to have a deductible so that first losses are born by the insured. Crop insurance usually has a deductible based on incomplete available coverage. For example, if maximum coverage is 85% of expected revenue, then the implied deductible is 15%. For multiperil crop policies, RMA also requires that good farming practices be followed, meaning that production methods must be used that allows the crop to make normal progress to maturity and produce at least the production guarantee (Risk Management Agency, 2013a). Certainly, what constitutes good farming practices can be difficult to define and monitor on an individual producer basis.

Of prime interest is whether the presence of crop insurance influences farmers' chemical use. This interest results because chemical use may impact the environment. Moral hazard arguments could be made to suggest that chemical use that is protective in nature, such as use of insecticides and fungicides, may decrease with crop insurance usage. However, the exact nature of crop insurance impacts on chemical use depends on the nature of the production function (Horowitz and Lichtenberg, 1993). Some studies find that crop insurance increases chemical use (Horowitz and Lichtenberg, 1993), whereas others find that crop insurance reduces chemical use (Smith and Goodwin, 1996). In some cases, perhaps the majority, crop insurance impacts on chemical use will be small. At this point it is not possible to unequivocally state the impacts on chemical usage of crop insurance.

Crop insurance may also impact acreage decisions. Acreage impacts generally would not be viewed as a case of moral hazard, but acreage impacts may be a general concern of public policy. Subsidized crop insurance may increase the attractiveness of the subsidized crop relative to crops that have no insurance. This effect could come from substitution of insured crops with crops without insurance (Nelson and Loehmann, 1987). Studies that have examined crop insurance impacts on acreage generally have found modest impacts (Wu, 1999; Goodwin *et al.*, 2004). For example, Goodwin *et al.* (2004) found that a 30% decrease in premiums result in a 1% increase in Midwest corn acres and 1% increase in northern plains barley production.

Farmer's Demand for Crop Insurance and Subsidies

Theories of demand suggest that risk-averse farmers will purchase crop insurance that is priced in an actuarially fair manner. Because actuarially fair insurance has total premiums equal to expected payments, farmers can purchase insurance that reduces risks without any reduction in expected returns, but instead simply trades off some higher for some lower revenue outcomes resulting in more stability. As a goal of RMA is to price insurance such that policies are actuarially fair, theory would suggest that many farmers would purchase federally subsidized crop insurance even without subsidy.

However, participation in federal crop insurance has not occurred without significant subsidies to premiums. Legislation in 1980, 1994, 2000, and 2008 increased subsidies, resulting in higher participation in each case. Studies suggest that increases in crop insurance subsidies result in a relatively small increase in crop insurance participation (Goodwin, 1993). In 2012, federal subsidies amounted to 62% of total premium (see **Table 3**), meaning that farmers pay 38% of total premium. At that level, insurance purchases should result in farmers receiving net gains from crop insurance purchases.

However, a number of reasons can be given for the relatively low demand for crop insurance in the absence of subsidy. Many of those reasons revolve around development of average ratings across heterogeneous producers. Total premiums are priced to an average level of risk and those farms with below average risk will pay relatively more for the risk reductions offered by the crop insurance product. Hence, farmers with below-average risk will not purchase crop insurance without significant subsidies. Another reason may be that the farmers have other options for risk management, including the production of multiple crops, use of pricing hedging tools, and holding financial reserves.

Use of subsidies then leads to the question: Why subsidize crop insurance? Assuming that crop insurance is priced in an actuarially fair manner, farmers in aggregate receive income transfers from crop insurance in addition to the risk protection offered from the crop insurance policies. This then leads to the question of why taxpayers should provide income subsidies to farmers. This is a continuing debate. Usual reasons given for subsidies include the systematic nature of agricultural losses, leading to the need for government involvement. Use of crop insurance may also have other societal benefits, such as assuring a more reliable food supply. Also, governments are involved in the subsidy of many insurance products, including flood, bank deposit, unemployment, and disability insurances. For a variety of reasons, private solutions in insurance markets may not be publicly desirable. In any case, debate on governmental involvement in crop insurance likely will continue.

Crop Insurance Outside the United States

This article has focused on use of crop insurance in the United States. Crop insurance has been used extensively in many countries around the world, including Brazil, Costa Rica, India, Japan, Mexico, and the Philippines (Hazell, 1992). When crop insurance is subsidized, a remarkably consistent set of issues arise from those of the United States' case, including (1) low participation in crop insurance occurs; (2) adverse selection, moral hazard, and other ratings problems arise; and (3) crop insurance losses are systematic in nature.

A problem that presents larger issues outside the United States is in measuring yields. Farms in developing countries are often small, lacking the means for accurately measuring yields. Moreover, histories of farm yields that can be used to determine yield risk do not exist. Both of these issues then lead to problems implementing crop insurance in developing countries. This has led to more of a reliance on weather-based

insurances and area-based contracts in developing crop insurance contracts in developing countries (Skees *et al.*, 1999). Of course, use of weather or index contracts introduces issues of correlation between the index on which crop insurance is based and actual yield. Whether or not these contracts will be successful is an open question.

Summary

Crop insurance provides important risk management protection to farmers. Over time, this risk management protection has been provided with heavy government involvement, including standardization and rating of products, pricing crop insurance policies, and reinsurance of crop insurance companies. Issues common to all insurance markets occur in crop insurance, and issues related to the systemic risk further complicate the provision through private markets alone. It has unique features that reset each year with annual prices of the underlying insured commodities and due to the single-price feature across participants and delivery channels. The degree of subsidy involved in its provision seems to be a key point of contention, but this issue should also be viewed in the context of the political environment that includes considerations of ad hoc disaster assistance and its use to motivate other desirable policy outcomes as well. In any case, it has become the primary cornerstone for many farmers' risk management activities and has also become one of the main features of farm program legislation debate. It is expected that crop insurance markets and products will continue to become more sophisticated through time and that innovations will continue, but some form of public participation will also continue for the foreseeable future due to the underlying nature of crop revenue risk.

© 2014 Elsevier Inc. All rights reserved.

Glossary

Biotic-pollination When pollen is delivered to stigmas by animal vectors such as insects.
Cross-pollination The transfer of pollen from an anther of the flower of one plant to a stigma of the flower of another plant.
Pollination The main mode of sexual reproduction in plants, which occurs when the transfer of pollen (male) from the anther of a flower to a stigma (female) results in fertilization which produces seeds and, in some cases, fruits.
Pollination dependency A measure of the level of impact that animal pollination has on the productivity of a particular (crop) plant species.
Self-pollination The transfer of pollen from an anther to a stigma of the same flower.
Wind-pollination When pollen is transported by wind, this is also called anemophily.

Introduction

Pollination is the main mode of sexual reproduction in plants, which occurs when the transfer of pollen (male) from the anther of a flower to a stigma (female) results in fertilization which produces seeds and, in some cases, fruits. Pollination is, therefore, an important input in the production of the marketable goods of many crops and can have a substantial impact on production. Pollination by animals in particular is a vital component in global agricultural economies by increasing crop productivity and profits. However, some of the main animal pollinators, such as bees, hoverflies, and butterflies, are in a state of long-term decline in some regions of the world, thereby threatening the stability and security of this ecosystem service. This article presents a brief overview of the main modes of pollination in globally important crops, highlighting the yield and economic benefits of animal pollination in particular. The main drivers of animal pollination service declines are then reviewed along with possible measures to mitigate these declines.

Modes of Pollination

Within crops there are several widely observed modes of pollination. Self-pollination whereby flowers of the plant are capable of fertilizing themselves is the most simplistic and often occurs in plants such as peas with enclosed flowers. However, most crops require pollen transfer between different flowers to successfully fertilize or benefit from external agents increasing their rate of self-pollination. In many crops pollen grains are light enough to be transferred effectively by wind with some crops, such as wheat, relying largely on wind pollination to successfully pollinate. Approximately 75% of globally important crops benefit from biotic pollination whereby animals transfer pollen between flowers or increase the rate of self-fertilization that occurs (Klein *et al.*, 2007). In some crops, biotic pollination by particular animals is essential to the production of marketable output. This is especially important to crops where the pollen is too heavy or sticky to move via the wind (e.g., almond *Prunus dulcis*), where there are separate male and female flowers (e.g., kiwifruit) and where pollen must come from a different cultivar (pollinizer) to produce fruit (e.g., rabbiteye blueberries, *Vaccinium virgatum*) (Free, 1993). Biotic pollination is usually performed by bees and flies, many of which have evolved to feed exclusively on floral pollen and nectar, but butterflies, beetles, birds, bats, and even some terrestrial mammals (e.g., palm squirrel; Chakravarthy and Thyagaraj, 2012) can provide pollination services to commercial crops (Klein *et al.*, 2007).

Globally, domesticated honeybees (*Apis* spp.) are widely utilized to provide pollination services to a wide variety of crops, particularly in large-scale systems (e.g., rapeseed) where abundant pollinators are required. However, some studies have demonstrated that honeybees are not always the most effective pollinators of crops, either by collecting nectar from flowers without contacting the anthers (e.g., apples, *Malus domestica*; Thompson and Goodall, 2001), displaying foraging preference for noncrop plants over some crops or simply finding some unattractive (e.g., pears, Stern *et al.*, 2004). Another widely observed group of pollinators are bumblebees (*Bombus* spp.), which are effective pollinators of many small fruits (e.g., raspberries, *Rubus idaeus*; Willmer *et al.*, 1994) and are widely domesticated to provide pollination services to crops that honeybees cannot effectively pollinate (e.g., tomatoes, *Solanum lycopersicum*; Banda and Paxton, 1991). Other pollinators have also been domesticated to provide more specialist pollination services to certain crops. These include alfalfa leafcutter bees (*Megachile rotundata*) that are used to pollinate alfalfa and mason bees (*Osmia* spp.), which have recently been domesticated to provide pollination services to some fruit crops (Bosch and Kemp, 2002).

Although domesticated pollinators can be readily managed to provide pollination services to a wide range of crops, pollination services by wild insects are increasingly thought to be important to crop production even in intensive cropping systems, such as muskmelon (*Cucumis melo*) production in Pennsylvania, USA (Winfree *et al.*, 2008). In many tropical countries feral honeybees, stingless bees (*Meliponina* sp.), and solitary bees are important contributors to crop pollination in

 doi:10.1016/B978-0-444-52512-3.00020-6

small holder systems. Other plants have more specialized pollination systems, such as figs (*Ficuscarica*) which are exclusively pollinated by fig wasps (*Blastophaga scripta*), which have evolved in parallel to the tree (Free, 1993). Many species of flies can also act as effective pollinators, notably *Cecidomyiid* spp., and *Ceratopogonid* midges that are the primary pollinators of cocoa, and hoverflies such as *Eristalis tenax* (Klein *et al.*, 2007). Ants are also known to be effective pollinators of a few tropical crops, such as mango (*Mangifera indica*; Carvalheiro *et al.*, 2010). In some rare circumstances where high value crops are grown beyond their native range, such as cherimoya (*Annona squamosa*) grown in Spain, there are no suitable insect pollinators available, necessitating that producers employ labor-intensive artificial pollination methods (Gonzalez *et al.*, 2006). Artificial pollination is usually accomplished by directly applying pollen to floral stigmas by hand using brushes (Pinillos and Cuevas, 2008); however, recent engineering advances have resulted in cost-effective pollen sprays for use in small orchards (Sakomoto *et al.*, 2009).

Benefits of Pollination

It is estimated that 75% of globally important crops benefit from biotic pollination in various ways, from directly increased yields to greater crop quality or other agronomic benefits (Klein *et al.*, 2007). Most overtly, biotic pollination directly increases fruit seed set in many crops compared with other modes of pollination alone (e.g., pears, *Pyrus communis*; Nyeki and Stolesz, 2003), resulting in greater overall production. This is especially important to crops that cannot self-pollinate, many of which require biotic pollination to effectively transfer pollen between neighboring plants (Free, 1993). Similarly, in many crops, biotic pollination produces fruits with greater weight compared with those produced by wind and self-pollination alone, increasing the total market output per hectare. Recent studies have demonstrated that pollination by insects can increase the proportion of marketable oil content in rapeseed (*Brassica napus*; Bommarco *et al.*, 2012). Biotic pollination can also increase the speed and synchronization of fruit maturity, resulting in easier, more efficient harvesting (e.g., linseed, *Linum usitatissimum*; Williams *et al.*, 1991). In some highly productive crops, such as sweet peppers (*Capsicum annum*) grown in glasshouses, this increased maturity can even result in additional harvests per year (Shipp *et al.*, 1994).

Beyond direct increases in output, biotic pollination can also significantly improve fruit quality in certain crops. For instance in strawberries (*Fragaria* × *ananassa*), pollination of all anthers by insects is required to produce fruit of an acceptable shape (Chagnon *et al.*, 1993). Besides economically significant quality factors, biotic pollination can improve the nutrient content (e.g., apples; *M. domestica*; Volz *et al.*, 1996), and taste quality (e.g., tomatoes, *S. lycopersicum*; Hogendoorn *et al.*, 2010) in some crops. Biotic pollination can also provide more long-term agronomic benefits to crop producers. By transferring pollen between different plants, crop pollination can reduce inbreeding effects within crops, which may help improve disease resistance (Free, 1993) and reduce crop abortion rate (e.g., almond, *P. dulcis*; Martinez-Garcia *et al.*, 2012). A study on persimmon (*Diospyros kaki*) tree productivity found that trees receiving ample pollination from insects also grew at a quicker rate, probably because the plant was forced to increase its nutrient uptake to support greater yields (George *et al.*, 1995).

Although pollination can benefit many plants, it is possible that biotic pollination may negatively impact productivity in some crops. For instance, if excessively pollinated, crop trees may become overburdened with fruits, requiring costly thinning by hand or chemical induction to prevent damage to the tree or excessive nutrient use. In other crops, notably pineapples and some varieties of citrus fruit (*Citrus* sp.) and cucumber (*Cucumis sativus*), biotic pollination can result in seed production which can leave the product unmarketable (Free, 1993). As most noncrop flowering plants also benefit from biotic pollination (Ollerton *et al.*, 2011), the prevalence of abundant pollinators can also encourage the propagation of many weeds.

Crop Dependency on Biotic Pollination

Although biotic pollination can have significant benefits to crop productivity, most crop plants will produce some marketable output through self and wind pollination alone. Nonetheless biotic pollination is often essential to produce profitable outputs in many crops (e.g., blackcurrants, *Ribes nigrum*; Denisow, 2004). This section presents an overview of the total yield benefits of pollination to different crop types (**Table 1**), highlighting the general trends and exceptions within each group.

Fruit Crops

As a group, the majority of fruit crops are dependent on pollination to produce marketable yields. Several tree fruit crops, notably apple (*M. domestica*), plum (*Prunus domestica*), and figs (*Ficus carica*), are largely self-incompatible and very highly dependent on animal pollinators to transfer pollen between flowers from different trees. Yields of most other tree fruits, including avocado, peach, pear, plum, and sour cherry, can increase by 500–900% by animal pollinators transferring pollen between plants and flowers as wind pollination is often insufficient to successfully transfer enough pollen. By contrast, the benefits of biotic pollination to persimmon trees (*D. kaki*) can vary substantially with some varieties being able to set fruit entirely through self and wind pollination, whereas other cultivars can double yields with ample biotic pollination (George *et al.*, 1995; Free, 1993). Citrus fruits (*Citrus* sp.) also vary in their need for biotic pollination; although some species, such as mandarin produce more and larger fruits when cross-pollinated by insects (Schneider *et al.*, 2009), varieties of other citrus crops can set more desirable seedless fruits with parthenocarpy, making biotic pollination largely undesirable (Free, 1993).

Small fruits largely benefit from biotic pollination to more moderate extents than other fruits as many are self-compatible, have small, light pollen grains, require fewer grains per stigma to fertilize, and produce multiple anthers per flower allowing them to set fruit even if not all stigmas are fertilized.

Table 1 Benefits of biotic pollination to selected globally significant crops

Crop	*Benefits of biotic pollination*	*Approximate yield lost without biotic pollination (%)*[a]	*Effective pollinators*[b]
Almond	Higher nut set	65	Honeybees, mason bees
Apple	Greater fruit set and weight, higher nutrient content	65	Mason bees, Honeybees
Buckwheat	Greater seed set	65	Honeybees
Citrus fruits	Increased fruit weight (some varieties)	5	Honeybees
Cocoa	Greater number of pods, greater pod weight	95	Midges
Coffee	Higher bean set and weight, fewer misshapen beans	25	Honeybees, stingless bees
Faba bean	Increased seed set and weight	25	Long-tongued bumblebees
Mango	Increased fruit set	65	Honeybees, stingless bees
Raspberry	Increase druplet number, fruit set, and weight	25	Bumblebees, honeybees
Rapeseed	Higher oil content, greater pod set, and weight	25	Honeybees
Seed cotton	Increased boll number, seed weight, and lint weight	25	Honeybees
Soybean	Increased pod set and weight	25	Bumblebees, honeybees
Strawberry	Greater fruit weight, less malformed fruit	25	Bumblebees, honeybees, mason bees, *Andrena* sp.
Sunflower	Higher seed set, greater oil content per seed	25	Honeybees, solitary bees
Tomato	Greater fruit weight, enhanced taste	25	Bumblebees

[b]Adapted from Klein, A.M., Vaissiere, B.E., Cane, J.H., *et al.* 2007. Importance of pollinators in changing landscapes for world crops. Proceedings of the Royal Society B – Biological Sciences 274 (1608), 303–313.

Nonetheless, visits by insects are often required to produce crops of marketable quality, particularly in strawberry (*Fragaria* × *ananassa*) which will set malformed, unmarketable fruit if only partially pollinated (Chagnon *et al.*, 1993). Biotic pollination is also important to increase fruit set in currants sufficiently to produce profitable output, despite their often strong degree of self-compatibility (Denisow, 2004). Blueberries and cranberries (*Vaccinium* spp.) benefit substantially from cross-pollination between different cultivars, increasing their fruit set and weight significantly over self-pollination. In temperate regions, bumblebees (*Bombus* sp.) are widely observed to be the most effective pollinators of most small fruits (Delaplane and Mayer, 2000). The only significant small fruit crop that does not benefit from pollination is grape (*Vitis vinifera*), which is highly self-compatible and readily pollinated by wind alone (Free, 1993).

Kiwifruit (*Actinidia deliciosa*) in particular, which has separate male and female plants, is highly reliant on insect visitors, usually honeybees and bumblebees to transfer pollen between plants of the two sexes. Several other fruit crops are highly self-incompatible or benefit substantially from cross-pollination, such as passion fruit (*Passiflora edulis*) and mango (*M. indica*), both of which produce significantly heavier fruits when cross-pollinated by insects (Bos *et al.*, 2007; Carvalheiro *et al.*, 2011). Commercial triploid banana (*Musa acuminata*) cultivars by contrast are often sterile and naturally produce fruit without any influence from biotic pollination (Free, 1993).

Vegetable Crops

Many of the most common vegetable crops, such as carrot, brassica, and onion do not benefit from insect pollination services to produce marketable output; however, pollination is often important to ensure ample seed set when breeding. Yields of most fruiting vegetables benefit significantly from biotic pollination. In most cucurbits (*Curcurbita pepo* – pumpkins, squash, zucchini, etc.), melons (*C. melo*), and watermelons (*Citrulus lanatus*), plants produce separate male and female plants that require pollen transfer from male to female flowers to produce fruits. These crops are highly dependent on biotic pollination which is typically provided by honeybees, wild solitary bees or, in North and South America, by squash bees, which have evolved to specialize on cucurbits (Klein *et al.*, 2007). Tomatoes (*S. lycopersicum*) and eggplants (*Solanam melongena*) by contrast are self-compatible but benefit moderately from biotic pollination when larger bodied bees vibrate their flowers in order to gather pollen, which is naturally sticky and heavy, dislodging additional pollen onto the stigma (Gemmill-Herren and Ochieng, 2008). Honeybees are too small to perform this kind of pollination ('buzz pollination'), so most commercial pollination is performed by bumblebees such as *Bombus impatiens*, particularly in enclosed glasshouse systems where honeybees are difficult to manage (Delaplane and Mayer, 2000). Although managed bumblebees are widely used in glasshouse systems, pollination by vibrating wands is still practiced in Australia where bumblebees cannot be introduced, although efforts persist to commercially domesticate a suitable native pollinator. Stingless bees, (*Meliponini*), though small, have been shown to be effective buzz pollinators for a number of tropical vegetable cropping systems (Slaa *et al.*, 2006).

Edible Oil and Proteinaceous Crops

Edible oil crops are a wide range of usually unrelated crops produced for oils extracted from their fruits and seeds. Many of these crops, notably seed cotton (*Gossypium* sp.), coconut (*Cocos nucifera*), sunflower (*Helianthus annuus*), and rapeseed (*B. napus*/*B. rapa*) are among the most widely grown crops

globally (FAO, 2013). Sunflowers have one of the two pollination systems, in most oil producing cultivars the flower switches between the male and female phases, whereas in hybrid production, specifically bred male and female lines are planted within the same field. Both benefit from insect visitation to optimize pollen transfer to female plants (Free, 1993). Rapeseed and canola are highly self-compatible and readily set pods with wind and self-pollination; however, their high nectar concentration makes them attractive to insects which can increase pollen transfer, thereby increasing the total marketable yield by 20% (Bommarco *et al.*, 2012). Rapeseed is attractive to a wide diversity of pollinating insects and although wild insects can be significant, managed honeybees are thought to provide a more reliable and stable service to larger fields (Rader *et al.*, 2009 but see Rader *et al.*, 2011; Woodcock *et al.*, 2013). Pollination in coconut, which has separate male and female flowers, produces similar increases in yield through greater drupe set (Meléndez-Ramírez *et al.*, 2004). Some edible oil crops gain very little benefit from pollination, such as linseed (*L. usitatissimum*) (Williams *et al.*, 1991), whereas olive (*Olea europaea*), is entirely wind pollinated (Klein *et al.*, 2007) and some, specially bred cultivars of rapeseed can also set ample yield from wind pollination alone (Free, 1993). In seed cotton, biotic pollination benefits production of both utilized outputs, resulting in a 20% increase in total seed weight and a 16% increase in lint production (Rhodes, 2002).

Stimulant Crops

Both the major stimulant crops, cocoa (*Theobroma cacao*) and coffee (*Coffea arabica* and *C. canephora*), benefit from biotic cross-pollination between plants to produce good quality yields. In cocoa, although bees have been observed to provide pollination services in some regions, the majority of pollination services are provided by midges (*Cecido myiid* and *Ceratopogonid* spp.). Both species of coffee benefit from insect visitation, however, despite their lighter pollen grains; *C. canephora* is thought to be slightly more dependent on insect pollination than *C. arabica* due to greater self-incompatibility (Free, 1993; Klein *et al.*, 2003). Field studies have indicated that pollination produces both greater bean set and weight by ~20% and reduces the occurrence of misshapen pea berries by 27% (Ricketts *et al.*, 2004; Klein *et al.*, 2003).

Nut Crops

Yields of most nut crops benefit to a great extent from biotic pollination, often by increasing the total number of nuts produced, as is seen in almond (Klein *et al.*, 2012). Brazil nuts (*Bertholletia excelsa*) in particular are highly dependent on pollination by larger bodied bees (e.g., carpenter bees, *Xylocopa* sp.) to produce marketable produce (Cavalcante *et al.*, 2012; Klein *et al.*, 2007). Although chestnut (*Castanea sativa*) is mostly wind pollinated, as a self-incompatible crop, insect visitation can still result in economically significant increases in crop yield (Free, 1993). Of the most widely grown nut crops (Klein *et al.*, 2007) only walnuts (*Juglans* sp.) and some cultivars of peanuts (*Arachis hypogaea*) are known to produce nuts completely by self and wind pollination.

Pulse Crops

Several pulse crops, notably soybean (*Glycine max*) and faba bean (*Vicia faba*), are often primarily self-pollinated due to their tightly enclosed flowers which place the anthers in direct contact with the stigma. Pollination of soybeans by Africanized honeybees has been observed to increase yields by 50% under experimental conditions, with bee-pollinated flowers producing more and heavier pods than enclosed plants (Chiari *et al.*, 2005). In faba beans, cross-pollination by insects has also been demonstrated to improve both yield and disease resistance (Suso, 2012). By contrast, biotic pollination has no effect on the yields of peas (*Pisum sativum*), lentils (*Lens esculenta*), and chickpeas (*Cicer arietinum*) and very little in cowpea (*Vigna unguiculata*). Other pulses such as runner beans (*Phaseolus coccineus*) have more open flowers that directly benefit from biotic pollination (Łabuda, 2010).

Spice Crops

Among the crops grown for condiment or spice products are several species of the plant family *Umbelliferae*, notably fennel (*Foeniculum vulgare*), caraway (*Carum carvi*), and coriander (*Coriandrum sativum*), which are characterized by numerous small flowers with each flower producing multiple seeds. Visitation of these flowers by foraging insects helps transfer pollen among the many flowers, resulting in substantial increases in seed set (Free, 1993). Owing to the arrangement of its anthers making self-pollination impossible, vanilla (*Vanilla planifolia*) relies entirely on biotic pollination for pod set, although in many regions this must be done via hand pollination (Free, 1993).

Cereal Crops

Most arable grain crops, including the global staples of wheat, rice, and maize do not benefit from biotic pollination, instead relying entirely on self and wind pollination to produce seeds (Klein *et al.*, 2007). The only exception is the pseudocereal Buckwheat (*Fagopyrum esculentum*), which is self-incompatible and benefits greatly from insect pollination to set seed (Taki *et al.*, 2011).

Root and Tuber Crops

The marketable components of vegetables grown for the roots and tubers, such as potato (*Solanum tuberosum*) and cassava (*Manihot esculenta*) are not known to benefit from insect pollination (Klein *et al.*, 2007). As potato tubers propagate vegetatively, most commercial varieties of potato have a reduced ability to flower and breeders do not select for traits that make the flower attractive to pollinators. Although insects are capable of pollinating these flowers, pollination in many of these plants is done by hand to ensure genetic purity.

Sugar Crops

Although visited by several insects, sugar beet (*Beta vulgaris*) is not known to benefit from biotic pollination as their flowers are highly self-compatible and effectively pollinated by self

Table 2 Economic value of pollination services to global regions

Region	*Total value of crop production (€bn)*	*Value of pollination services (€bn)*	*Pollination services as a % of total value*	*Regional % of global pollination service value*
Africa	137.5	11.9	9	8
Asia	881	88.1	10	58
Europe	216.7	22	10	14
North America	176.8	17.9	10	12
South America	187.7	11.6	6	8
Oceania	18.8	1.3	7	1
Total	1618.5	152.8	9.5

and wind pollination alone (Free, 1993). As a grass, sugar cane (*Saccharum officinarum*) is entirely pollinated by wind.

Other Crops

Apart from edible crops, yields of several important plants grown for commercial seed production benefit to a great extent from insect pollination, often by specialist insects. Lucerne seed (*Medicago sativa*) yields, in particular, are heavily dependent on insect pollination by specialist alfalfa leafcutter bees (*M. rotundata*), which are better able to access the nectaries and pollen of lucerne flowers (Delaplane and Mayer, 2000). Similarly, several species of clover (*Trifolium* sp.) are widely bred for planting as nitrogen fixing cover crops or hay and require insect visitation to effectively cross-pollinate. Red clovers (*Trifolium pratense*), among other species, have long, deep flowers that cannot be accessed by most short-tongued bees and instead require longer-tongued species such as the bumblebee *Bombus hortorum* (Bommarco *et al.* 2011).

Economic Valuation of Crop Pollination

It is widely recognized that the benefits of pollination services to yields carry considerable economic value, particularly as insect-pollinated crops are on average significantly more valuable per ton than other crops (Gallai *et al.*, 2009). Quantifying these benefits can play an important role in decision making and illustrating the impacts of changes in service availability (e.g., Ricketts *et al.*, 2004). Although a range of methods have been developed to estimate the economic value of pollination services, the most common is the dependence ratio method that estimates value based on the proportion of crop production lost in the absence of pollination services at a field (e.g., Olschewski *et al.*, 2006) and market scale (e.g., Losey and Vaughn, 2006). On the basis of this method, the global economic value of biotic pollination to crop production in 2005 was estimated at €153bn in enhanced production alone (Gallai *et al.*, 2009). Notably this estimate does not include the benefits to vegetable seed production and crops not traded on monetary markets, such as subsistence growing and plants used by traditional people (Ashworth *et al.*, 2009). More than half (58%) of this value originates from Asia (**Table 2**), in particular China and India, although valuation hotspots can be found in Brazil, Western USA, and several parts of Japan (Lautenbach *et al.*, 2012; Gallai *et al.*, 2009). In some developing nations, pollination-driven production can form a substantial proportion of national agricultural Gross Domestic Product (GDP) such as in Ghana where cocoa production forms a major component of both agricultural and total national GDP. As such pollination services, valued at US$788m formed ~0.5% of total national GDP, substantially higher than in other more developed nations (Ngo *et al.*, 2012) (**Figure 1**).

The value of pollination services as estimated by various sources (Gallai *et al.*, 2009; Losey and Vaughn, 2006; Smith *et al.*, 2011; Jian-Dong and Wen-Feng, 2011; Brading *et al.*, 2009; Gallai and Vaissière, 2009) was converted into US$ and divided by total national GDP (current US$) using the data from World Bank (2012).

Within crop groups, these economic benefits are particularly high for fruit crops and fruiting vegetables which encompass ~66% of global pollination service value (**Table 3**) due to their high market prices and high dependence on pollination to produce an optimal yield, and within edible oilseeds due to the high global volume of the crops grown (Gallai *et al.*, 2009).

The economic benefits of added crop productivity also vary in scale and form between different stakeholders; for producers, increased production and market quality can increase profits per hectare substantially (Kasina *et al.*, 2009; Winfree *et al.*, 2011). This can be especially valuable to producers in lower income countries, where agriculture often forms a more important component of local economies (Lautenbach *et al.*, 2012). Consumers by contrast benefit from reduced prices as a result of added production. Globally, the total value of this price reduction is estimated to be between €153bn and €422bn, greater than the value of additional produce itself (Gallai *et al.*, 2009).

Beyond these direct production benefits, animal pollination services also provide significant value to producers in costs avoided. In the absence of sufficient animal pollination services, producers often utilize labor-intensive artificial pollination using paintbrushes (e.g., Partap and Ya, 2012), vibrating wands (e.g., Hogendoorn *et al.*, 2010), or sprays (e.g., Sakomoto *et al.*, 2009), which can substantially increase producer costs. For instance, Allsopp *et al.* (2008) estimated that the total costs of replacing pollination services to tree fruit crops in South Africa's Western Cape region is at between

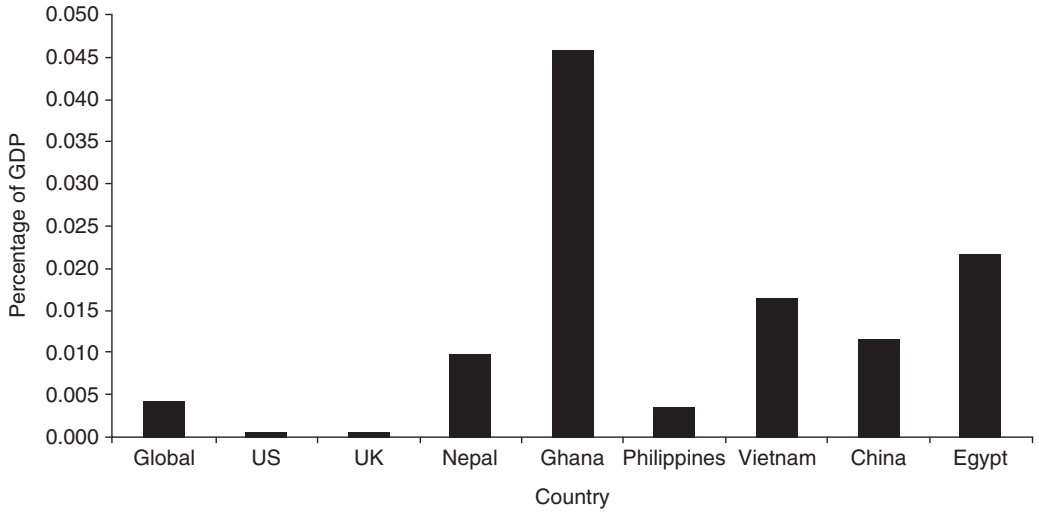

Figure 1 Proportion of total national GDP arising from insect-pollinated crops for selected countries and global average. Compiled by H. Ngo from FAO data.

Table 3 Economic value of pollination services to crop groups

Crop group	*Total value of crop production (€bn)*	*Value of pollination services (€bn)*	*Pollination services as a % of total value*	*Regional % of global pollination service value*

Roots and tubers	98	0	0	0
Total	1618.5	152.8	9.5	

Source: Adapted from Gallai, N., Vaissière, B.E., 2009. Guidelines for the economic value of pollination services at a national scale. Available at: http://www.internationalpollinatorsinitiative.org/uploads/POLL%20VALUE%20NATIONAL%20MANUAL.pdf

$77m and $433m (US) annually. Furthermore artificial pollination may not be viable for all crops, such as raspberry where hand pollination produces lower quality fruits compared with insect pollination (Kempler *et al.*, 2002). Pollination services provided by wild animals can also reduce the need to hire managed honeybees for crop pollination. For example, hiring additional honeybees to replace pollination services provided by wild pollinators in the watermelon plantations in New Jersey would cost producers an estimated $200 000, effectively doubling the expenditure on managed pollination services (Winfree *et al.*, 2011).

In addition to these economic benefits, production added by pollination services has a substantial impact on human diets. Globally, animal-pollinated crops form 35% of the total crop production (Klein *et al.*, 2007) and a loss of pollination services would result in a reduction of total crop production by 3–8% even if highly pollinator-dependent crops were replaced with pollinator-independent ones (Aizan *et al.*, 2009). Although the majority of crop-based calories and protein in the human diet derive from pollinator-independent crops, animal-pollinated crops are the main sources of vegetable fats and several major micronutrients. Consequently, ~41% of vitamin A, 20% of vitamin C, 32% of carotenoids, and 20% of fluorides in global diets are thought to derive from production added by insect pollination (Eilers *et al.*, 2011).

Threats to Pollination Services

Many of the benefits of biotic pollination are directly tied to the abundance and diversity of pollinating animals, with shortfalls linked to localized yield losses (Bommarco *et al.*, 2011), limitations (Groeneveld *et al.*, 2010), and instability (Garibaldi *et al.*, 2011a), despite growing global yields (Aizen *et al.*, 2008). In recent decades, although global honeybee stocks have increased (Aizen and Harder, 2009), there have been widely reported declines in the number of managed

honeybees in many western countries (Potts *et al.*, 2010a; van Engelsdorp and Meixner, 2010) and many wild pollinators have suffered observed declines across the world (Potts *et al.*, 2010b). Contrary to these declines in available pollinators there has been a 300% rise in the global area of insect-pollinated crops (Aizen and Harder, 2009); and insect-pollinated crops have become increasingly important to the agricultural economies of many developed and developing countries (Lautenbach *et al.*, 2012). Furthermore, horticultural crops, many of which are insect pollinated, form ~20% of agricultural exports from the developing world, twice that of cereals and further crop diversification in developing nations is increasingly regarded as an effective means of alleviating poverty (Lumpkin *et al.*, 2006). Unlike the historical increase in cereal production, this expansion of production in the developing world has come primarily from increases in the area cropped, not from yield increases.

Declines in wild pollinators have been primarily driven by the loss, degradation, and fragmentation of seminatural habitat within agricultural landscapes as large monocultures have replaced numerous small fields, leaving many pollinating insects with little forage or nesting resources (Feon *et al.*, 2010). Although mass flowering crops can provide highly abundant forage for some pollinating insects (Westphal *et al.*, 2003), these resources are not available for much of the flying season and can, over several years, increase competition for later season resources with other species (Diekötter *et al.*, 2010). These effects are exacerbated by high applications of herbicides and fertilizers, which can significantly alter plant communities by changing the soil composition or by killing plants (Henle *et al.*, 2008; Carvalheiro *et al.*, 2011). Consequently, it is widely observed that pollination services to crops often decline substantially with greater distance to the seminatural habitat (Garibaldi *et al.*, 2011b) and less diverse habitat within the wider landscape (e.g., Klein *et al.*, 2012; Taki *et al.*, 2011).

Within managed honeybees, which are less sensitive to habitat loss than wild pollinators (Winfree *et al.*, 2010), declines are primarily thought to be driven by the spread of parasites and pests, in particular the mite *Varroa destructor* which can directly spread many diseases and viruses to afflicted bees (van Engelsdorp and Meixner, 2010). Several of these viruses have been suggested as possible causes of widely observed colony collapse disorders within North America (Cox-Foster *et al.*, 2007), although the exact cause remains as yet unidentified. The fungi *Nosema* sp. and foulbrood (e.g., *Melissococcus plutonius*) also represent significant pressures on honeybee colonies by reducing breeding success and killing many honeybee brood if left unchecked (van Engelsdorp and Meixner, 2010). The prevalence of disease within wild bees is less well understood; however, several studies have demonstrated that diseases can spill over from managed to wild populations and even between different species, further increasing pressures on wild populations (Meeus *et al.*, 2011; Otterstatter and Thomson, 2011). The rising costs of treating these diseases, coupled with falling honey prices and poor availability of effective *Varroa* treatments in some countries (e.g., UK; Formato *et al.*, 2010) have driven sharp declines in the number of beekeepers in many countries (Potts *et al.*, 2010b).

Wider use of insecticides across the world is also thought to have negatively affected both wild pollinators and managed honeybees by causing direct mortality (Scott-Dupree *et al.*, 2009) or reducing breeding success (Lu *et al.*, 2012), metabolic efficiency (Hawthorne and Dively, 2011), or foraging efficiency (Yang *et al.*, 2008). These impacts are further exaggerated by exposure to multiple pesticides (Gill *et al.*, 2012). Recent research has supported this concern by demonstrating reduced pollination services in landscapes with greater chemical inputs (Brittan *et al.*, 2010). In some regions, such as parts of China, extreme pesticide use has completely eradicated native pollinators and deterred beekeepers from placing their hives in affected areas, forcing producers to resort to labor-intensive hand pollination or switch to pollinator-independent crops (Partap and Ya, 2012). Climate change may also play a role in the declines of pollinating insects by driving the spread of new pests, such as the Asiatic hornet in Europe, where native honeybees have no defenses (Marris *et al.*, 2011) or by disrupting plant-pollinator phenological networks (Schweiger *et al.*, 2010). Outbreeding between imported honeybee hives and local strains could potentially cause the loss of desirable local traits (Jaffe *et al.*, 2010). Finally, the introduction of managed pollinators into an area may also increase resource competition with native wild pollinators (Goulson and Sparrow, 2009 but see Garibaldi *et al.*, 2013).

Management of Pollination Services

Despite widely observed declines in pollinators, there are a number of ways that producers can manage their operations to enhance or stabilize pollination service provision. Foremost, managed pollinators can be brought in to provide concentrated pollination services to crops particularly to large-scale fields or orchards, where services from wild pollinators alone may be too unstable. Honeybees in particular are effective pollinators of many open-grown crops globally although several other species have been domesticated for pollination service provision in particular crops or cropping systems. Large numbers of honeybees are particularly important for pollination in almond plantations in California, USA (Klein *et al.*, 2012) and in large-scale systems where high numbers of visitors are required (Rader *et al.*, 2009; Isaacs and Kirk, 2010). In some crops that are less attractive to honeybees (e.g., pears) or which honeybees may not visit legitimately (e.g., apples), careful management such as introducing some hives later than others can result in greater overall pollination services by slowing the rate of nectar robbing behavior and increasing competition (Stern *et al.*, 2001, 2004).

Although honeybees are highly numerous and will forage on most crop plants, other managed pollinators are more effective service providers in some crops or production systems. Bumblebees (*Bombus* sp.) have been observed to be more effective pollinators of several soft fruit crops (Isaacs and Kirk, 2010; Denisow, 2004; Stubbs and Drummond, 1997; Willmer *et al.*, 1994) and forage earlier in the day and at lower temperatures than honeybees, increasing their efficiency further in cooler climates (Isaacs and Kirk, 2010). Long-tongued bumblebees are widely observed to be the

primary pollinators of several deep flowered crops, notably faba beans (Aouar-Sadli *et al.*, 2008; Benachour *et al.*, 2007) and red clover (Bommarco *et al.*, 2012). With their smaller colony sizes, bumblebees are less vulnerable to overheating and resource depletion when confined in enclosed systems than honeybees (Delaplane and Mayer, 2000), making them ideal glasshouse pollinators and highly effective on several crops such as tomatoes (Banda and Paxton, 1991), strawberry (Ji-Larn *et al.*, 2006), and sweet pepper (Ercan and Onus, 2003).

Some solitary bee species have also been domesticated to provide more specialist pollination services to certain crops. Mason bees (*Osmia* sp.) in particular, have been demonstrated to be several times more effective per individual than honeybees in apples, almonds (Vicens and Bosch, 2000a,b), blueberries (Stubbs and Drummond, 1997), and sweet cherries (Bosch *et al.*, 2006). Mason bees are primarily bought as cocoons and incubated at different temperatures to ensure emergence in time with peak crop flowering (Sheffield *et al.*, 2008a); however, it is possible that introduced individuals may find or enhance wild populations if careful management to provide suitable nesting sites and postcrop forage is provided (Stubbs and Drummond, 2001; Sheffield *et al.*, 2008b). For instance, Sheffield *et al.* (2008b) found that sowing late flowering bigleaf lupins (*Lupinus polyphyllus*) in Nova Scotia apple orchards significantly increased breeding success of *Osmia lignaria* introduced to provide pollination. Another domesticated solitary bee is the alfalfa leafcutter bee (*M. rotundata*), which has been domesticated primarily to pollinate lucerne, its preferred forage, but can also effectively pollinate other crops such as blueberry (Stubbs and Drummond, 1997).

Although managed pollinators can provide ample pollination services to crops, in many cropping systems, wild insects are often as or more important service providers (Winfree *et al.*, 2008; Garibaldi *et al.*, 2011b; Holzschuh *et al.*, 2012; Garibaldi *et al.*, 2013). In some crops, notably strawberries (Chagnon *et al.*, 1993) and sunflowers (Carvalheiro *et al.*, 2011; Greenleaf and Kremen, 2006) a mix of wild pollinators and managed honeybees has been demonstrated to provide the highest yields as the two groups provide complementary pollination of the same flowers. Diverse wild pollinator communities often provide insurance against losses of key service providers as the remaining species become more able to exploit crop resources (Winfree *et al.*, 2010; Klein *et al.*, 2012) and produce more stable crop yields between years (Garibaldi *et al.*, 2011b). Recent studies have also demonstrated that honeybees are largely incapable of fully substituting for losses of wild insect pollination services in most crop systems, intensive or small holder (Garibaldi *et al.*, 2013). Furthermore, diverse pollinator communities allow producers to grow more diverse crops within their holdings or between years as part of rotations by providing an array of pollinators with different foraging habits and preferences.

There are a number of ways that producers can manage their holding to maintain and encourage healthy wild pollinator populations. Foremost, providing natural habitat in close proximity to crops can provide foraging and nesting resources to wild insects when crops are not in bloom. Morandin and Winston (2006), for instance, recommend that ~30% of the surrounding landscape is left uncultivated to optimize pollination services to mass flowering crops. Ricketts *et al.* (2008) also demonstrate that pollination services fall substantially at distances of more than 1000 m from a seminatural habitat. Where maintaining large sections of habitat is not possible or practical, including fallow land as part of crop rotations has been demonstrated to encourage pollinators even in intensive landscapes (Kuussaari *et al.*, 2011). Alternatively, many plants used as unharvested cover crops, such as red clover, can add forage diversity to the landscape. Pollinators can also be encouraged within fields by planting diverse nectar flower margins or tussocky grasses at the edge of crops left untreated by pesticides (Pywell *et al.*, 2011; Potts *et al.*, 2009; Lye *et al.*, 2009). In several developed nations many of these practices are subsidized as part of national agri-environmental schemes, providing an added incentive to adopt these practices (Kleijn *et al.*, 2006), and can provide additional on-farm benefits such as soil quality maintenance and erosion control (Wratten *et al.*, 2012). A recent study in South Africa has also demonstrated that allowing flowering weeds to remain in sunflower fields enhanced pollination service benefits by a greater extent than the negative effects of the weeds themselves and produced a more even pollination throughout the field (Carvalheiro *et al.*, 2011). Reducing herbicide use and grazing intensity on grasslands can also help promote pollinator diversity by allowing more diverse flower communities to establish (Hatfield and LeBuhn, 2007; Scheper and Kleijn, 2011).

Conclusion

As the global population continues to grow and demand for food production increases, the areas of flowering crops needed to meet this demand will continue to expand and so will the reliance on pollination services. Pollinators provide a wide range of production, economic, and health benefits and they will need to be increasingly considered as a legitimate agricultural input contributing to food security.

Glossary

Age at first calving The age from the date of birth to date of first calving.
Breed A group of animals related by descent and having similar appearance, behavior, and most of the other characteristics.
Crossbreeding The mating of animals of different breeds. Crossbreeding is followed for breeding animals for milk and meat production. In India, zebu nondescript cows are crossed with exotic breeds, like Holstein Friesian, Brown Swiss, and Jersey bulls or their semen, to enhance the milk production potential of the progeny.
305-days milk yield Milk yield produced up to 305 days of lactation.
Dry period The period from the date of dry to the date of next calving.
Gestation period The period from the date of conception to the date of calving.
Lactation length The period from the date of calving to the date of dry.
Lactation milk yield Total milk yield produced by a cow or a buffalo in complete lactation.
Service period The period from the date of calving to the date of conception.
Species A group of individuals that have certain common characteristics, which distinguish them from other group of individuals and are capable of interbreeding and producing fertile offspring.

Cattle

Animals belonging to the phylum Chordata (backbone animals), class Mammalia (milk giving), order Artiodactyla (even toed and hoofed), suborder Ruminatia (cud-chewing), family Bovidae (hollow unbranched horn), and genus *Bos* (ruminant quadrupeds) are cattle.

Cattle can be broadly classified into dairy and beef cattle. Dairy cattle are cows (adult females) that are bred for their ability to produce milk. Beef cattle are bred for meat production.

Zoological Classification of Cattle

Table 1 shows the zoological classification of cattle.

Domestication of Cattle

Time: 6000–6500 years BC.
Location: Old World.
Reason: Religious.
How: Aurochs.

Number of chromosome pairs of cattle: 30.

Body Weights

Body weight in cattle ranges from 25–45 kg at birth to 464–653 kg at maturity.

Common Terms Related to Cattle

Terms related to cattle that are commonly used are given in Table 2.

Utility

Milk, meat, draught, manure, and hide.

Table 1 Zoological classification of cattle

Kingdom	Animalia
Phylum	Chordata (backbone animals)
Class	Mammalia (milk-giving)
Order	Artiodactyla (even toed and hoofed)
Suborder	Ruminatia (cud-chewing)
Family	Bovidae (hollow unbranched horn)
Genus	*Bos* (ruminant quadrupeds)
Species	1. *Bos indicus* (humped cattle)
	2. *Bos taurus* (without any hump)

Important Breeds of Cattle

Although there are approximately 800 cattle breeds around the globe, a few important cattle can be studied by classifying them as *Bos indicus* and *Bos taurus*. Historically, there was little distinction between dairy and beef cattle, with the same stock often being used for both meat and milk production, but now cattle are bred specifically for meat or milk purpose.

Dairy cows generally are of the species *B. taurus*. A few important *taurus* breeds are listed in Table 3. Cows of *B. indicus* species, also known as zebu cattle, are known for their sturdy nature, disease resistance, draught ability, and adaptation to high temperature. Moreover, a few breeds of zebu cattle are good milkers. According to the Food and Agriculture Organization Manual entitled 'Zebu Cattle of India and Pakistan' (1953), Indian cattle breeds are grouped into six categories as given in Table 4. The meat of adult cattle is known as beef and cattle raised for meat production are beef cattle. A few important beef cattle breeds are listed in Table 5.

In India, zebu nondescript cows are crossed with exotic breeds, like Holstein Friesian, Brown Swiss, and Jersey bulls or their semen, to enhance the milk production potential in the progeny. A few important crossbred cattle are listed in Table 6.

Depending on the cattle species, breed, and region of location of an animal, age of puberty differs. Accordingly, breeding or artificial insemination of heifers is usually done around 13 months of age in *taurus* breeds in temperate regions, whereas it is done around 25–30 months of age in *zebu*. A cow's gestation period is approximately 9 months. Average ranges for some economic traits in Indian cattle are given in Table 7.

Jersey

Origin: This breed was developed from the island of Jersey in the English Channel off the coast of France.

Distinguishing characters:

- Jersey is one of the oldest dairy breeds, having been reported by authorities as being purebred for nearly six centuries.
- The color in Jerseys may vary from a very light gray or mouse color to a very dark fawn or a shade that is almost black. Both the bulls and females are commonly darker around the hips and around the head and shoulders than on the body.

Table 2 Common terms related to cattle

Common name of animal	*Male*	*Female*	*Young*	*Group*	*Act of mating*	*Gestation/pregnancy period*	*Name of giving birth*
Dairy cattle	Bull	Cow/heifer	Calf	Herd/drove	Serving	9 months	Calve

Table 3 List of *Bos taurus* dairy cattle breeds

S. No.	*Name of the breed*	*Native breed*	*Specific region*	*Remarks*
1	Brown Swiss	Switzerland	–	Dairy breed
2	Holstein Friesian	Holland	Province of North Holland and West Friesland	Dairy breed
3	Jersey	British Isles	Island of Jersey	Dairy breed
4	Guernsey	Guernsey	British Channel Island of Guernsey	Dairy breed
5	Ayrshire	Scotland	Scotland	Dairy breed

Table 4 Different breed groups of Indian cattle breeds

Group	*Particulars*	*Name of breeds*
First	Lyre-horned gray cattle with white foreheads, prominent orbital arches, and faces with flat or dished profiles	Kankrej, Malvi, Kherigarh, and Tharparkar
Second	Shorthorned, white or light gray with coffin-shaped skull, orbital arches, and faces with convex profiles	Hariana, Ongole, Mewati, Nagauri, Rathi, Krishna Valley, and Gaolao
Third	Heavy body build, pendulous dewlap and sheath, prominent forehead, spotted red or white, or various sheds of red and white	Gir, Red Sindhi, Sahiwal, Deoni, Nimari, and Dangi
Fourth	Mysore-type cattle. Forehead is prominent and the horns emerge from the top of the poll fairly close together in upward and backward direction	Amritmahal, Hallikar, Kangayam, Khillari, Alambadi, and Bargur
Fifth	Heterogeneous mixture – small, black, red, or dun cattle often with large patches and white markings. Found in Himalayan region and rugged terrain	Ponwar and Siri
Sixth	Those animals that cannot fit in any of the five groups	Dhanni (Pakistan)

Source: Reproduced from Banerjee, G.C., 2010. A Textbook of Animal Husbandry, eigth ed. New Delhi: Oxford and IBH publishing Co. Pvt. Ltd.

- Age at first calving: 26–30 months.
- Milk yield: 5000–8000 kg.

Holstein Friesian

Origin: This breed originated in Holland.

Distinguishing characters:

- Holsteins are large, stylish animals with color patterns of black and white or red and white.
- Holstein heifers can be bred at 15 months of age, when they weigh approximately 800 lb. It is desirable to have Holstein females calve for the first time between 24 and 27 months of age.
- Milk yield: 7200–9000 kg.
- This is by far the best diary breed among exotic cattle regarding milk yield. On an average, it gives 25 l of milk per day, whereas a crossbreed Holstein Friesian cow gives 10–15 l of milk per day.
- It can perform well in coastal and delta areas.

Red Sindhi

- Home tract of Red Sindhi breed of cattle is Sindh province (Karachi and Hyderabad) in present Pakistan. Portion of Sindh called Kohistan is real breeding tract of this breed.
- Mainly available in Punjab, Haryana, Karnataka, Tamil Nadu, Kerala, and Odisha.
- Milk production in institutional herds ranges from 1250 to 1800 kg per lactation (Indian Council of Agricultural Research, 2008; Banerjee, 2010).

Sahiwal

- Breeding tract is Montgomery district of Pakistan, which is now known as Sahiwal district.
- In India, pedigree herds found in Punjab, Haryana, Uttar Pradesh, Delhi, Bihar, and Madhya Pradesh.
- First lactation milk yield ranges from 1597 to 2125 kg (Indian Council of Agricultural Research, 2008).

Gir

- Mainly found in the Gir forest areas of south Kathiawar in Gujarat (India).
- Also found in Maharashtra and adjacent Rajasthan.
- Milk yield ranges from 1250 to 1800 kg.

Deoni

- Mainly found in western parts of Andhra Pradesh in India.
- Cows are good milk producers and bullocks are good for work.

Table 5 List of beef cattle breeds

S. No.	*Name of the breed*	*Native breed*
1	Angus	Scotland
2	Nellore	India

Table 6 List of crossbred cattle in India

Name	*Inheritance*		*Place*
	Bos indicus *(cows)*	Bos taurus *(bull)*	
Taylor	Local cows	Ayrshire	Patna (Bihar)
Jersind	Kankrej, Gir, Hariana, Sahiwal, and Red Sindhi	Holstein Friesian, Brown-Swiss, Jersey, and Guernsey	Allahabad (Uttar Pradesh)
Karan Swiss	Sahiwal and Red Sindhi	Brown-Swiss	NDRI, Karnal (Haryana)
Karan Fries	Tharparkar	Holstein Friesian	NDRI, Karnal (Haryana)
Sunandini	Local nondescript	Brown-Swiss	Kerala
Frieswal	Sahiwal	Holstein Friesian	Military Dairy Farm

Abbreviation: NDRI, National Dairy Research Institute.

Table 7 Averages range for some economic traits in Indian cattle

Breeds	*Age at first calving (months)*	*First calving interval (days)*	*First service period (days)*	*First lactation milk yield (kg)*	*First lactation length (days)*
Hariana	41–49	434–523	136–303	730–1170	257–315
Sahiwal	38–48	418–473	136–189	1597–2125	228–330
Tharparkar	39–53	418–474	130–183	1326–2139	268–317
Red Sindhi	39–49	436–562	152–158	1312–1694	284–345
Gir	44–61	456–541	135–259	1125–1859	230–394
Ongole	36–42	529–637	210–241	658–999	279
Deoni	47–55	456–472	173–192	818–1041	282–302

Source: Reproduced from Indian Council of Agricultural Research, 2008. Handbook of Animal Husbandry. New Delhi: Indian Council of Agricultural Research.

Hariana

- The native tract of this breed is Haryana state in India. Mainly found in Hisar, Rohtak, and Gurgaon district of Haryana, Delhi, Uttar Pradesh, and western parts of Madhya Pradesh.
- The average milk yield is between 600 and 800 kg per lactation.
- Most popular dual-purpose breed of cattle in Indo-Gangetic plains. Bullocks are powerful for road transport and rapid plowing (Indian Council of Agricultural Research, 2008).

Tharparkar

- Tharparkar breed of cattle belongs to Tharparkar district in Sindh province in Pakistan.
- Also found in Jodhpur and Jaisalmer district of Rajasthan in India.
- First lactation milk yield ranges from 1326 to 2139 kg.

Kankrej

- Native of this breed is southeast of Rann of Kutch in Gujarat.
- Bullocks are fast, active, and strong. Good for plow and cart purpose.

Kangayam

- Also known by other names of Kanganad and Kongu, although the name Kangayam is well known. These cattle are bred in the southern and southeastern area of the Erode district of Tamil Nadu in India.
- Best suited for plowing and transport. Withstands hardy conditions.

Amritmahal

- Mainly found in Karnataka.
- Best suitable for plowing and transport.

Hallikar

- Mainly found in Tumkur, Hassan, and Mysore districts of Karnataka.
- Bullocks are strong, well spirited, quick, and steady in field as well as on road.

Umblacherry

Origin: Tanjore district in Tamil Nadu.

Distinguishing characters:

- This breed has similar characters as Kangayam.
- Bulls are used for plowing in Tanjore delta area.
- Calves are red in color when born and become gray in color after 6 months of age.
- Cows are poor milker with average milk yield of 300 kg per lactation.
- Male animals are good for hard work.

Cow Nutrition

Average rates of daily feeding of concentrates and green and dry fodder assumed for different stages of life of cattle are given in Table 8.

Heifer

Heifer is a young female cow before she has had her first calf. Heifers are selected on the basis of progeny testing, i.e., the potential of the sire and milk production of the dam, their proper growth, good health, and freeness from any genetic abnormality.

Bull

Bulls contribute 50% of the inheritance to the next generation. Most of the genetic improvement in a population comes through proper bull selection. It is not very practicable to have intense selection of the females for breeding, i.e., almost all the heifers will have to be reared and used for breeding in a situation where age at first calving and calving interval are not optimum. Hence, most care is to be given for bull selection.

Cattle Breeding

The following points describe the different aspects of scientific breeding of cattle and buffaloes.

- Reproduction is an important consideration in the economics of cattle production. In the absence of regular breeding and calving at the appropriate time, cattle rearing will not be profitable. A healthy calf each year is the usual goal. This is possible only by increasing the reproductive efficiency of the animals.
- Successful reproduction encompasses the ability to mate, the capacity to conceive and to nourish the embryo, and deliver the viable young ones at the end of a normal gestation period. In fact, interruption in this chain of events

Table 8 Average rates of daily feeding of concentrates and green and dry fodder assumed for different age groups of cattle

Cattle		*Concentrate (kg)*	*Green fodder (kg)*	*Dry fodder (kg)*
Crossbred (milch)		2.75	20.0	6.00
Females >3 years of age	Improved cows (milch)	1.20	10.00	6.00
	Other milch cows and not calved even once	0.125	3.5	3.16
Males >3 years of age		0.17	4.96	5.65
Males <3 years of age	Crossbred (young stock)	1.50	10.00	2.00
	Other young stock	0.016	1.58	1.47

Source: Reproduced from Banerjee, G.C., 2010. A Textbook of Animal Husbandry, eigth ed. New Delhi: Oxford and IBH publishing Co. Pvt. Ltd.

leads to failure of the cow to conceive, the death of the embryo, or premature delivery of the fetus.

- Mating – The reproductive efficiency is a complex phenomenon controlled by both genetic and nongenetic factors, the nongenetic factors being climate, nutrition, and level of management. The reproductive efficiency varies not only between species and breeds but also among the animals within the same breed. Even the best feeding and management cannot coax performance beyond the genetic limit of an inferior animal. Improving the genetic merits of livestock populations is important at all levels of management. A sound breeding program is a necessary part of the total animal production system.
- Factors affecting breeding efficiency of cattle are as follows:
  1. Number of ova – The first limitation on the breeding efficiency of fertility of an animal is the number of functional ova released during each cycle of ovulation. Ovulation is the process of shedding ovum from the Graafian follicle. In the case of cow, usually a single ovum is capable of undergoing fertilization only for a period of 5–10 h. Therefore, the time of mating in relation to ovulation is important for effective fertilization.
  2. Percentage of fertilization – The second limitation is fertilization of ova. Failure to fertilize may result from several causes. The spermatozoa may be few or low in vitality. The service may be either too early or too late so that the sperms and eggs do not meet at the right moment to result in fertilization.
  3. Embryonic death – From the time of fertilization till birth, embryonic mortality may occur due to a variety of reasons. Hormone deficiency or imbalance may cause failure of implantation of fertilized ova, which die subsequently. Death may occur as a result of lethal genes for which the embryos are homozygous. Other causes may be accidents in development, overcrowding in the uterus, insufficient nutrition, or infections in tile uterus.
  4. Age of first pregnancy – Breeding efficiency may be seriously lowered by increasing the age of first breeding. Females bred at a lower age are more likely to appear stunted during the first lactation, but their mature size is affected little by their having been bred early.
  5. Frequency of pregnancy – The breeding efficiency can be greatly enhanced by lowering the interval between successive pregnancies. The wise general policy is to breed for the first time at an early age and to rebreed at almost the earliest opportunity after each pregnancy. In this way, the lifetime efficiency is increased. Cows can be rebred in 9–12 weeks after parturition.
  6. Longevity – The length of life of the parent is an important part of breeding efficiency because the return over feed cost is greater in increased length of life. Also, it affects the possibility of improving the breed. The longer the life of the parents, the smaller the percentage of cows needed for replacement every year.
- Management practices to improve breeding efficiency of cattle are listed below:
  1. Keep accurate breeding records of dates of heat, service, and parturition. Use records in predicting the dates of heat and observe the females carefully for heat.
  2. Breed cows near the end of heat period.
  3. Have females with abnormal discharges examined and treated by a veterinarian.
  4. Call a veterinarian to examine females not settled after three services.
  5. Get the females checked for pregnancy at the proper time after breeding.
  6. Buy replacements only from healthy herds and test them before putting them in your herd.
  7. Have the females give birth in isolation, preferably in a parturition room and clean up and sterilize the area once parturition is over.
  8. Follow a program of disease prevention, test, and vaccination for diseases affecting reproduction and vaccinate the animals against such diseases.
  9. Practice a general sanitation program.
  10. Supply adequate nutrition.
  11. Employ the correct technique.
  12. Provide suitable shelter management.
  13. Detect silent or mild heat by using a teaser bull.

Cattle Population

According to the FAOSTAT in the year 2010, there were 1428.7 million cattle stock. Among those with approximately 210.2 million cattle stock, India is the country with the largest cattle population, contributing approximately 14.7% to the world, followed by Brazil (209.5 million), the United States (93.9 million), and China (83.8 million).

Housing Systems

In the UK, there are three main options available for housing dairy cattle.

- Cubicles
- Straw (loose) yards
- Kennels.

Cubicles and straw yards are most commonly used in Great Britain. There are advantages and disadvantages to both housing systems. Both systems can work equally well with regard to cow welfare and productivity, with much of the variation caused by management decisions and actions.

An efficient management of cattle will be incomplete without a well-planned and adequate housing of cattle. Improper planning in the arrangement of animal housing may result in additional labor charges and curtail the profit of the owner. During erection of a house for dairy cattle, care should be taken to provide comfortable accommodation to an individual cow. Also important are (1) proper sanitation, (2) durability, (3) arrangements for the production of clean milk under convenient and economic conditions, etc.

Location of dairy buildings

The points to be considered before starting construction of dairy buildings are as follows:

1. Topography and drainage: To offer a good slope for rainfall and drainage for the wastes to avoid stagnation within dairy building, construction should be at a higher elevation. A leveled area requires less site preparation and

thus lesser cost of building. Low lands and depressions and proximity to places of bad odor should be avoided.
2. Soil type: Fertile soil should be spared for cultivation. Foundation soils, as far as possible, should not be too dehydrated or desiccated. Such a soil is susceptible to considerable swelling during rainy season and exhibits numerous cracks and fissures.
3. Exposure to the sun and protection from wind: A dairy building should be located to a maximum exposure to the sun in the north and minimum exposure to the sun in the south and should have protection from prevailing strong wind currents, whether hot or cold. Buildings should be placed in a way that direct sunlight can reach the platforms, gutters, and mangers in the cattle shed. As far as possible, the long axis of the dairy barns should be set in the north–south direction to have the maximum benefit of the sun.
4. Accessibility: Easy accessibility to the buildings is always desirable. A cattle shed should be situated by the side of the main road, preferably at a distance of approximately 100 m.
5. Durability and attractiveness: It is always attractive when the buildings open up to a scenic view and add to the grandeur of the scenery. Along with this, durability of the structure is obviously an important criterion in building a dairy.
6. Water supply: Abundant supply of fresh, clean, and soft water should be available at a cheap rate.
7. Surroundings: Areas infested with wild animals and dacoits should be avoided. Narrow gates, high manger curbs, loose hinges, protruding nails, smooth-finished floor in the areas where the cows move, and other such hazards should be eliminated.
8. Labor: Honest, economic, and regular supply of labor should be available.
9. Marketing: Dairy buildings should only be in those areas from where the owner can sell his products profitably and regularly. They should be in a position to satisfy the needs of the farm within no time and at reasonable price.
10. Electricity: Electricity is the most important sanitary method of lighting a dairy. As a modern dairy always handles electric equipment that is economical, it is desirable to have an adequate supply of electricity.
11. Facilities, labor, and food: Feed storages facilities such as hay stacks, silo and manure pits should be quite near to the cattle barn for most efficient utilization of labour.
Some important features of feed stores are:

- Feed storages should be located near the center of the cow barn.
- Milk house should be located almost at the center of the barn.
- Center cross alley should be well designed with reference to feed storage, the stall area, and the milk house (Banerjee, 2010).

Types of housing

In India except in some organized dairy farms- owned by government, co-operatives or military- the prevalent practice is to tie the cows with rope on a Katcha floor. It is quite easy to understand that unless cattle are provided with good housing facilities, the animals will move too far in or out of the standing space, defecating all around and even causing trampling and wasting of feed by stepping into the mangers. The animals will be exposed to extreme weather conditions, all leading to bad health and lower production (Banerjee, 2010).

There are wide varieties of conditions, ranging from close confinement to little restrictions except at milking time, where dairy cattle may be successfully housed. However, two types of dairy barns are in general use at the present time.

1. The loose housing barn in combination with some type of milking barn or parlor.
2. The conventional dairy barn.

Loose housing system

It is a system where animals are kept loose except at the time of milking and treatment. The system is most economical. Some features of loose housing system are as follows.

- Cost of construction is significantly lower than the conventional type.
- It is possible to make further expansion without change.
- Facilitates easy detection of animal in heat.
- Animals feel free and therefore prove more profitable with even minimum grazing.
- Animals get optimum exercise, which is extremely important for their better health.
- Overall, better management can be rendered.

Cattle shed

The entire shed should be surrounded by a boundary wall of 5 ft height from three sides and manger, etc. on one side. The feeding area should be provided with 2–2.5 ft of manger space per cow. All along the manger, there shall be a 10-in.-wide water trough to provide clean drinking water. The water trough thus constructed will also minimize the loss of fodders during feeding. Near the manger, under the roofed house, 5-foot-wide floor should be paved with bricks having a little slope.

Shed for calves

On one side of the main cattle shed there should be a fully covered shed of 10×15 sq ft area to accommodate young calves. Such sheds with suitable partitioning may also serve as calving pen under adverse climatic conditions. Beyond this covered area, there should be a 20×10 sq ft open area having boundary wall so that calves may move there freely. In this way, both calf and cattle sheds will need in all a 50×50 sq ft area for 20 adult cows and followers. If one has limited resources, they can build ordinary, Katcha/semikatcha (mud/semimud) boundary walls; however, feeding and water trough should be cemented ones.

Conventional dairy barn

The conventional dairy barns are comparatively costly and are now becoming less popular day by day. However, by this system, cattle are more protected from adverse climatic condition.

The following barns are generally needed for proper housing of different classes:

- Dairy stock in the farm
- Cow houses or sheds

- Calving box
- Isolation box
- Sheds for young stocks
- Bull or bullock sheds.

Cow sheds

Cow sheds can be arranged in a single row if the number of cows is less – say, less than 10 – and in a double row if the herd is a large one. Ordinarily, not more than 80–100 cows should be placed in one building. In double-row housing, the stable should be so arranged that the cows face out (tail-to-tail system) or face in (head-to-head system) as preferred.

Advantages of tail-to-tail system:

- Under the average conditions, 125–150 man-hours of labor are required per cow per year. Study of time: Time motion studies in dairies showed that 40% of the expended time is spent in front of the cow, 25% in other parts of the barn and the milk house, and 60% of the time is spent behind the cows. Time spent at the back of the cows is four times more than the time spent in front of them.
- In cleaning and milking the cows the wide middle alley is of great advantage.
- Lesser danger of spread of diseases from animal to animal.
- Cows can always get more fresh air from outside.
- The head milkman can inspect a greater number of milkmen while milking. This is possible because milkmen will be milking on both sides of the gowala.
- Any sort of minor disease or any change in the hindquarters of the animals can be detected quickly and even automatically.

Advantages of head-to-head system:

- Cows make a better showing for visitors when heads are together.
- Cows feel easier to get into their stalls.
- Sunrays shine in the gutter where they are needed the most.
- Feeding cows is easier; both rows can be fed without back tracking.
- It is better for narrow barns.

Floor

The inside floor of the barn should be of some impervious material that can be easily kept clean and dry and is not slippery. Paving with bricks can also serve one's purpose. Grooved cement concrete floor is still better. The surface of the cowshed should be laid with a gradient of 1–1 14 in. from manger to excreta channel. An overall floor space of 65–70 sq ft per adult cow should be satisfactory.

Walls

The inside of the walls should have a smooth hard finish of cement, which will not allow any lodgment of dust and moisture. Corners should be round. For plains, dwarf walls, approximately 4–5 ft in height, and roofs supported by masonry work or iron pillars are best or more suitable. The open space in between supporting pillars serves for light and air circulation.

Roof

Roof of the barn may be of asbestos sheet or tiles. Corrugated iron sheets have the disadvantage of making extreme fluctuations in the inside temperature of the barn in different seasons. However, iron sheets with aluminum-painted tops to reflect sunrays and bottoms provided with wooden-insulated ceilings can also achieve the objective. A height of 8 ft at the sides and 15 ft at the ridge is sufficient to give the necessary air space to the cows. An adult cow requires at least approximately 800 cubic ft of air space under tropical conditions. To make ventilation more effective, continuous ridge ventilation is considered most desirable.

Manger

Cement concrete continuous manger with removable partitions is the best from the point of view of durability and cleanliness. A height of 1 ft to 4 in. for a high-front manger and 6–9 in. for a low-front manger is considered sufficient. Low-front mangers are more comfortable for cattle, but high-front mangers prevent feed wastage. The height at the back of the manger should be kept at 2 ft to 6–3 in. An overall width of 2–2.5 ft is sufficient for a good manger.

Alleys

The central walk should have a width of 5–6 ft exclusive of gutters when cows face out and 4–5 ft when they face in. The feed alley, in case of a face out system, should be 4 ft wide, and the central walk should show a slope of 1 in. from the center toward the two gutters running parallel to each other, thus forming a crown at the center.

Manure gutter

The manure gutter should be wide enough to hold all dung without getting blocked and be easy to clean. Suitable dimensions are 2 in. width with a cross-fall of 1 in. away from standing. The gutter should have a gradient of 1 in. for every 10 ft length. This will permit a free flow of liquid excreta.

Doors

The doors of a single-range cowshed should be 5 in. wide with a height of 7 ft, and for double-row shed the width should not be less than 8 in. to 9 ft. All doors of the barn should lie flat against the external wall when fully open.

Calving boxes

Allowing cows to calve in the milking cowshed is highly undesirable and objectionable. It leads to unsanitary conditions in milk production and spread of disease, like contagious abortion in the herd. Special accommodation in the form of loose boxes enclosed from all sides and with a door should be furnished to all parturient cows. It should have an area of approximately 100–150 sq ft. With ample soft bedding, it should be provided with sufficient ventilation through windows and ridge vent.

Isolation boxes

Animals suffering from infectious disease must be segregated soon from the rest of the herd. Loose boxes of approximately 150 sq ft are very suitable for this purpose. They should be situated at some distance from the other barns. Every isolation

box should be self-contained and should have separate connection to the drainage disposal system.

Sheds for young stocks

Calves should never be accommodated with adults in the cowshed. The calf house must have provision for daylight ventilation and proper drainage. Damp and ill-drained floors cause respiratory trouble in calves to which they are susceptible. For an efficient management and housing, the young stock should be divided into three groups, viz., young calves (aged up to one year), bull calves (the male calves over one year) and the female calves (above one year). Each group should be sheltered in a separate calf house or calf shed. As far as possible, the shed for the young calves should be quite close to the cow shed. Each calf shed should have an open paddock or exercise yard. An area of 100 sq ft per head for a stock of 10 calves and an increase of 50 sq ft for every additional calf will make a good paddock. It is useful to classify the calves below 1 year into three age groups, viz., calves below the age of 3 months, 3–6-month-old calves, and those more than 6 months of age, for a better allocation of the resting area. An overall covered space of:

1. 20–25 sq ft per calf below the age of 3 months,
2. 25–30 sq ft per calf from the age of 3–6 months,
3. 30–40 sq ft per calf from the age of 6–12 months and more, and
4. 40–45 sq ft for every calf above 1 year. Provision of water troughs inside each calf shed and exercise yard should never be neglected.

Bull or bullock shed

Safety and ease in handling a comfortable shed, protection from weather, and a provision for exercise are the key points while planning accommodation for bulls or bullocks. A bull should never be kept in confinement, particularly on hard floors. Such a confinement without adequate exercise leads to overgrowth of the hoofs creating difficulty in mounting and loss in the breeding power of the bull. A loose box with rough cement concrete floor approximately 15×10 ft in dimensions having an adequate arrangement of light and ventilation and an entrance 4 ft in width and 7 ft in height will make a comfortable housing for a bull. The shed should have a manger and a water trough.

If possible, the arrangement should be such that water and feed can be served without actually entering the bull house. The bull should have a free access to an exercise yard provided with a strong fence or a boundary wall of approximately 2 ft height, i.e., too high for the bull to jump over. From the bull yard, the bull should be able to view the other animals of the herd so that it does not feel isolated (Banerjee, 2010).

Cattle Milk Production

Although India was the largest milk-producing country in the world with respect to overall milk production from livestock by the year 2010, cow milk production was highest in the United States (87.5 million tons) followed by India (50.3 million tons), China (36.0 million tons), and Brazil (31.7 million tons).

Cow Meat Production

As cow is a motherly figure and worshipped as mother according to the Hindu religion, cow slaughter is banned in parts of India and remains a contentious issue in states where it is legal. In the year 2010, cow meat production was 64 275 698 ton.

Diseases in Cattle

Performance of cattle in the form of milk, meat, or hide production or reproduction is affected by a number of diseases that may be caused by bacteria, virus, or protozoa or may be due metabolic cause and nutritional deficiencies. A few important diseases of cattle are anthrax, black quarter, bovine abortions, bovine mastitis, cow pox, foot-and-mouth disease, hemorrhagic septicemia, leptospirosis, rinderpest, vibrionic abortion, and metabolic disorders.

Anthrax

- Anthrax is an acute, infectious febrile disease of virtually all animals and man. It is caused by *Bacillus anthracis*.

Symptoms:

- The disease may occur in a peracute, acute, or subacute form. In the first form, the animal dies suddenly, rarely showing any symptoms.
- In acute and subacute forms, there may be high rise in body temperature and signs of intense pain.

Black quarter (black leg)

The disease is common in areas with moderate rainfall and where dry-crop cultivation is common. Young animals in the prime of condition and 6 months to 3 years of age are affected more than others. Outbreaks generally occur with the onset of rains. True black quarter is caused by *Clostridium chauvoei*. Fever with redness of eye and hot painful swelling in the affected leg are some of the observed symptoms. A crepitating sound is heard on pressing the affected part of muscle. Death may occur in severe cases within 1–2 days.

Symptoms:

- The disease usually occurs in an acute form; affected animals die within 24–48 h of the onset of symptoms.
- There is high fever with a hot, tense, painful swelling, usually in one of the quarters, more often a hindquarter; however, such swelling may also occur in the other quarter before death. The swelling becomes cold and painless and crepitates on pressure due to the presence of gas in it.

Prevention and control:

- To prevent the spread of infection and contamination of the soil with spores of the causal organisms, carcasses of animals dead of black quarter should be either buried deep and covered over with lime or cremated.
- Administration of penicillin in repeated doses may be effective if injected before muscle damage has been caused.
- Use of black quarter vaccine protects animals against the disease for approximately a year. Animals should be

vaccinated with this approximately 3–1 month before the onset of rain.

Foot-and-mouth disease

- The food-and-mouth disease is a highly communicable disease affecting cloven-footed animals. It is characterized by fever and formation of vesicles and blisters in the mouth, udder, teats, and on the skin between the toes and above the hoofs.
- Animals recovered from the disease present a characteristically rough coat and deformation of the hoof.
- The disease spreads by direct contact or indirectly through infected water, manure, hay, and pastures.
- It is also conveyed by cattle attendants. It is known to spread through recovered animals, field rats, porcupines, and birds.
- Foot-and-mouth disease occurs in a relatively mild form in India and is seldom fatal. It occurs practically all the year round.

Symptoms:

- Fever with 104–105 °F temperature.
- Profuse salivation ropes of stringy saliva hangs from mouth.
- Vesicles appear in the mouth and in the interdigital space.
- Lameness observed.
- Crossbred cattle are highly susceptible to it.

Control and prevention:

- Heavy milch animals and exotic breeds of cattle bred for milk should be protected regularly.
- It is advisable to carry out two vaccinations at an interval of 6 months followed by an annual vaccination program.
- Isolation and segregation of sick animals. It should be informed immediately to the veterinary doctor.
- Disinfection of animal sheds with bleaching powder or phenol.
- Attendants and equipment for sick animals should be ideally separate.
- The equipment should be thoroughly sanitized.
- Proper disposal of leftover feed by the animal.
- Proper disposal of carcasses.
- Control of flies.

Hemorrhagic septicemia

This acute septicemic disease of cattle and buffaloes is widely prevalent in India. It occurs generally in low-lying areas periodically inundated by rainwater and in areas where irrigation facilities have developed. The causal organism, *Pasteurella multocida*, is a small Gram-negative coccobacillus, commonly called bipolar organism on account of the intensity with which it stains at the poles. Redness of eye and lancination along with fever; severe dyspnea; hot painful swelling at head, jowl region, or brisket region are observed. In severe cases sudden death may occur due to high fever and severe dyspnea.

Symptoms:

- The disease generally runs an acute course. Cattle and buffaloes often develop a highly septicemic condition and die within the course of approximately 24 h of infection.
- Affected animals show a high rise in body temperature.
- The lesions comprise hemorrhagic spots in the lymph nodes, on the serous membranes, and in other organs, including the inner lining of the heart; however, spleen is normal in size.
- The entire gut is highly inflamed and intensely red with bloody contents.

Treatment and prevention:

- Early cases of the disease are amenable to treatment with sulfonamides, notably sulfadimidine coupled with antibiotics, such as penicillin, but on account of the short course of the disease and its termination in sudden death, animals are seldom available in good time for treatment.
- Vaccination with the improved type of adjuvant vaccine, carried out approximately a month before the onset of rains, will protect the animals against the attack of the disease for approximately 1 year. In endemic areas, such vaccination should be carried out every year.

Bovine mastitis

- This disease is characterized by inflammation of the udder, resulting in changes in the udder tissue and its secretion.
- Infectious mastitis results from infection with one or more of the many organisms associated with cattle in all countries where dairy industry is well developed, and the disease is of great economic importance to milk producers.
- Clinically, the disease may be recognized as acute, subacute, or chronic, and these forms may depend on the type of the causal organism concerned. It may be accompanied by systemic disturbance, with a rise in body temperature of the affected animal and other febrile symptoms, but usually it occurs in the form of a localized involvement of the udder, with a progressive damage to the udder tissue.
- The milk is affected both in quality and quantity, and as a result of permanent impairment of the function of one or more quarters, milk production may cease altogether. Both cows and female buffaloes suffer from the disease.

Leptospirosis

Leptospirosis occurs in animals and humans in almost all parts of the world. Serological evidence indicates the prevalence of leptospires among domesticated animals in different parts of the country. The damage done to animal industry results from the death of animals in the acute stage of illness; stillbirth; abortion; stunning; decrease in weight (loss of meat); reduced milk production; and unthriftiness.

Causes and pathogenesis:

The causative organisms of leptospirosis belong to the genus *Leptospira*.

Symptoms:

- In cattle, it is an acute, often fatal, disease characterized by hemorrhage, hemoglobinuria, and icterus.
- Nonfatal infections are often characterized by fever, anemia, abortions, sterility, decreased lactation, and mastitis.

Rinderpest

- Rinderpest is the most destructive of the virus diseases of cloven-footed animals, such as cattle, buffaloes, sheep, goats, pigs, and wild ruminants. Its control was a major issue until recently all over the world.
- Organized efforts over half a century have brought about a total eradication of the disease in the western hemisphere.
- The disease still persists in Asian countries.
- The virus is found notably in the saliva, discharge from the eyes and the nostrils, and in the urine and feces.
- It is present in the circulating blood during the febrile stage and is later concentrated in different organs, especially in the spleen, lymph nodes, and liver. Outside the animal body, the virus is rapidly destroyed by direct sunlight and disinfectants. Cold preserves the virus.
- The virus is usually spread by contaminated feed and water.
- Rise in temperature up to 104–107 °F. Lacrimation and redness of the eyes.
- Foul odor from the mouth. Discrete necrotic foci develop in the buccal mucosa, inside lip, and on the tongue. Bloody mucoid diarrhea is noticed.

Vibrionic abortion of cattle

- This is a widely prevalent form of abortion in some countries and the causal organism is *Vibrio fetus*.
- The disease resembles *Brucella abortus* infection but is less severe in form. It is generally transmitted during natural service or artificial insemination with semen from infected bulls.

Diagnosis:

- Diagnosis is made by examination of uterine exudate and stomach contents of the fetus.
- The disease is usually self-limiting; infected animals develop active immunity after one abortion.

However, hygienic measures should be taken to prevent spread of the infection.

Table 9 Zoological classification of buffalo

Kingdom	Animalia
Phylum	Chordata (backbone animals)
Class	Mammalia (milk-giving)
Order	Artiodactyla (even toed and hoofed)
Suborder	Ruminatia (cud-chewing)
Family	Bovidae (hollow unbranched horn)
Genus	*Bubalus* (ruminant quadrupeds)
Species	1. *Bubalus bubalis* (all types of domestic river buffalo) 2. *Bubalus carabanesis* (swamp)

Metabolic diseases

Milk fever

- Milk fever, also known as parturient hypocalcemia and parturient paresis, is a disease that has assumed considerable importance with the development of heavy milking cows.
- Decrease in the levels of ionized calcium in tissue fluids is basically the cause of the disease.
- In all adult cows there is a fall in serum calcium level with the onset of lactation at calving.
- The disease usually occurs in 5–10 year old cows, and is chiefly caused by a sudden decrease in blood-calcium level, generally within 48 h after calving.

Symptoms:

- In classical cases, hypocalcemia is the cause of clinical symptoms. Hypophosphatemia and variations in the concentration of serum magnesium may play some subsidiary role.
- The clinical symptoms develop usually in 1–3 days after calving. They are characterized by loss of appetite, constipation, and restlessness, but there is no rise in temperature.

Buffalo

Animal belonging to the phylum Chordata (backbone animals), class Mammalia (milk giving), order Artiodactyla (even toed and hoofed), suborder Ruminatia (cud-chewing), family *Bovidae* (hollow unbranched horn), and genus *Bubalus* (ruminant quadrupeds) is buffalo.

Zoological Classification

Table 9 explains the zoological classification of buffalo.

Domestication

Time: 2500–2100 BC.

Number of Chromosome Pairs

Bubalus bubalis: 25.
Bubalus carabanesis: 24.

Common Terms Related to Buffalo

Terms related to buffalo that are commonly used are given in Table 10.

Table 10 Common terms related to buffalo

Common name of animal	*Male*	*Female*	*Young*	*Act of mating*	*Group*	*Gestation/pregnancy period*	*Name of giving birth*
Buffalo	Buffalo bull	Female-buffalo/buffalo cow	Calf	Serving	Herd	10 months	Calve

Utility

Milk, meat, draught, and manure.

Domestication

It has been suggested that buffaloes were in service of humans as early as 2500–2100 BC. The domesticated buffaloes can be classified into two main categories, i.e., (1) The swamp buffalo (chromosomes, $2n=48$) and (2) The river buffalo (chromosomes, $2n=50$). They belong to the same species, *B. bubalis*, but have very different habits. The former is more or less permanent inhabitant of marsh lands, where it wallows in mud and feeds on coarse marsh grass, and is found principally in Malaya, Singapore, the Philippines, Thailand, Indonesia, southern China, and other counties in the Far East. In the Philippines and some other countries, it is known as the Carabao and in Malaysia as the Kerban. The river type is the one found throughout India, Pakistan, Bangladesh, Nepal, and Sri Lanka. These are primarily milch animals (Banerjee, 2010). Water buffaloes were domesticated in India approximately 5000 years ago and in China approximately 4000 years ago. Two types are recognized on the basis of morphological and behavioral criteria – the river buffalo of the Indian subcontinent and further west to the Balkans and Italy and the swamp buffalo, found from Assam in the west through Southeast Asia to the Yangtze valley in China in the east.

Breeds

In India there are 13 well-defined breeds with standard qualities and with specific physical characters that differentiate them unmistakably from other types as may be found in various states of the country. On the basis of regions, the well-defined buffalo breeds are listed in Table 11.

Out of all these breeds, six breeds, viz., Murrah, Nili-Ravi, Jaffarabadi, Bhadawari, Surti, and Mehsana are high-quality milch breeds of the country and they all come from the northern and western parts of the country comprising the states of Punjab, Rajasthan, and Gujarat. The breeds of central and western parts are noted as draught purpose due to the fact that they have swamp as well as river characteristics.

Murrah

Home tract stretches around the southern parts of Haryana comprising the districts of Rohtak, Jind, Hisar, Jhajhar, Fatehabad, and Gurgaon and the Union Territory of Delhi. However, this breed has spread to almost all parts of the country and is either being bred in pure form or being used as improver breed for grading up local buffaloes. Murrah breed has even found an important place in the livestock industry of many developing countries like Bulgaria, the Philippines, Malaysia, Thailand, China, Indonesia, Bangladesh, Nepal, the former USSR, Myanmar, Vietnam, Brazil, and Sri Lanka. Milk yield varies from place to place depending on the management practices and environmental conditions under which animals are reared. Large herds have shown average yields as 1800 kg.

Housing – In the breeding tract, these buffaloes are kept in a mixed type of housing system. The buffaloes are tied to a tree or a pole in the open, but shelter is provided during extreme weather conditions. Houses are well ventilated and mostly made up of *pucca* (solid) walls with *katcha* (mud) floor.

Feeding – Animals are mostly stall fed. Berseem, oat, and mustard are the green fodders fed in Rabi season and pearl millet, sorghum, and cluster bean in Kharif season. In lean season, Murrah animals are maintained on wheat and pulse straws in conjunction with oilcakes and other concentrates. Mostly, women are engaged in buffalo rearing (80%), and all the activities pertaining to feeding, milking, cleaning, etc. are looked after by them. Calves are not weaned. Very few farmers rear bulls exclusively for breeding purpose. Natural service is mostly practiced in field.

Nili-Ravi

Nili and Ravi were two different breeds long before, but due to the passage of time and with intensive crossbreeding, the two breeds converted into a single breed named Nili-Ravi. Nili-Ravi buffaloes are found in almost all the districts, with major concentration in Amritsar, Gurdaspur, and Ferozepur districts of Punjab in India and in Lahore, Sheikhupura, Faizabad, Okora, Sahiwal, Multan, Bohawalpur, and Bahwalnagar districts of Punjab in Pakistan. However, due to good dairy characteristics of this breed in Pakistan, Nili-Ravi buffaloes are found in whole of Pakistan with major concentration in buffalo colony at Karachi. The average lactation yield in Nili-Ravi buffaloes range from 1688–2317 kg.

Banni, Kalahandi, and Chilika are newly registered buffalo breeds in India.

Banni

Home tract of this breed is Bhuj, Nakhatrana, Anjar, Bhaahau, Lakhpat, Rapar, and Khavdatalukas in Gujarat in India. Animals are heavily built with typical double and vertical coiling of the horn. Average age at first calving is approximately

40 months and average lactation milk yield is approximately 2857 kg in field conditions.

Kalahandi

Kalahandi buffaloes are dual type; they are used both for milk and draught purpose in Kalahandi and Rayagada districts of Odisha. Animals are medium sized; have long, strong, and half-circled horns with broad base; and are excellent in heat and drought tolerance.

Heat Tolerance

Although buffaloes are found in greatest numbers in the tropics, they have poor heat resistance and suffer real distress if worked during the heat of the day or if they are left to stand in the direct rays of the sun for long periods. Access to water or shade is essential for the well-being of buffaloes. It is customary to rest working buffaloes for several hours in the middle of the day and to allow them to wallow at that time and again in the early evening when the day's work is over. It is thus to be noted that sudden changes of temperature, especially the effect of cold winds and drought, may be extremely harmful to this species. Heat-regulating mechanism of buffaloes in comparison with cattle is less efficient. The difference may be due in part to the heavy coat of the cow preventing wetting of the skin but more probably to the fact that the thyroid–adrenal mechanism is less efficient in buffaloes (Banerjee, 2010).

Wallowing

It means rolling or floundering in mud or in water. The river breeds of Indian subcontinent prefer the clear water of streams and pools, bunching close together, but the swamp buffalo of China and southeast Asia likes to wallow in slime and mudhole, accommodating one animal or very few animals only. It is seldom that buffaloes are found in areas where there is no easy access to water. Although wallowing is not absolutely necessary for buffaloes to maintain themselves, they apparently wallow for two main reasons: to regulate body temperature and to control parasites. Moreover, there is no definite pattern of wallowing (Banerjee, 2010).

Buffalo's Nutrition

Average rates of daily feeding of concentrates and green and dry fodder assumed for different stages of life of buffalo are given in Table 12.

Buffalo Milk Production

In the year 2010, 92.51 million tons of buffalo milk was produced in the world. Buffalo milk production was the highest in India (62.40 million tons) followed by Pakistan (22.28 million tons).

Buffalo Meat Production

In the year 2010, buffalo meat production was 3 499 857 tons.

Goat

Animal belonging to the phylum Chordata (backbone animals), class Mammalia (milk-giving), order Artiodactyla (even toed and hoofed), suborder Ruminatia (cud-chewing), family Bovidae (hollow unbranched horn), and genus *Capra* is goat.

Zoological Classification of Goat

Table 13 explains the zoological classification of goat.

Domestication of Goat

Time: 9000–7000 BC.

Number of chromosome pairs of goat: 30 (*Capra hircus*)

Body Weights

Body weight in goat ranges from 2.5–3.5 kg at birth to 26–102 kg at maturity.

Table 13 Zoological classification of goat

Kingdom	Animalia
Phylum	Chordata (backbone animals)
Class	Mammalia (milk-giving)
Order	Artiodactyla (even toed and hoofed)
Suborder	Ruminatia (cud-chewing)
Family	Bovidae (hollow unbranched horn)
Genus	*Capra*
Species	*Capra hircus* (True goat including Bezoar)
	Capra falconeri (Markhor)
	Capra ibex
	Capra caucasica (Caucasian tur)
	Capra pyrenaica (Spanish ibex)

Common Terms Related to Goat

Terms related to goat that are commonly used are given in Table 14.

Utility

Milk, meat, fiber, manure, and hide.

Important Breeds of Goat

There are more than 100 breeds of goat around the world. These breeds could be grouped according to their utility, i.e., milk, meat, and fiber.

Dairy goats

Alpine

Alpine goats are known for their very good milking ability. They are multicolored and have no set markings. They have erect ears, horns, and have a dish face. The breed originated in the French Alps. Mature animals weigh approximately 61 kg or 125 lbs and are approximately 0.8 m or 30 in. tall at the shoulder. Alpine goats can range in color from white or gray to brown and black. Alpine goats are heavy milkers; the milk can be made into butter, cheese, soap, ice cream, or any other dairy product that cow's milk can produce. They are most often used for commercial milking. The French-alpine is also referred to as the Alpine Dairy goat and registration papers for this dairy goat use both designations, which are synonymous. These are hardy, adaptable animals that thrive in any climate while maintaining good health and excellent production. Alpine goats' milk has an average butterfat of approximately 3.5%. The face is straight.

Alpine colors are described by using the following terms:

- Cou Blanc – (coo blanc) literally 'white neck' – white front quarters and black hindquarters with black or gray markings on the head.
- Cou Clair – (coo clair) literally 'clear neck' – front quarters are tan, saffron, off-white, or shading to gray with black hindquarters.
- Cou Noir – (coo nwah) literally 'black neck' – black front quarters and white hindquarters. Sundgau – (sundgow) black with white markings, such as underbody, facial stripes, etc. Pied – spotted or mottled.
- Chamoisee – (shamwahzay) brown or bay – characteristic markings are black face, dorsal stripe, feet and legs and sometimes a martingale running over the withers and down to the chest. Spelling for male is chamoise. Two-tone Chamoisee – light front quarters with brown or gray hindquarters. This is not a coublanc or couclair, as these terms are reserved for animals with black hindquarters.
- Broken Chamoisee – a solid chamoisee broken with another color by being banded or splashed, etc. Any variation in the above patterns broken with white should be described as a broken pattern, such as a broken coublanc (Briggs and Briggs, 1980; American Dairy Goat Association, n.d.).

Anglo-Nubians

These goats were developed in England by crossing British goats with bucks of African and Indian origin. The Anglo-Nubian is an all-purpose goat, useful for meat, milk, and hide production. It is not a heavy milk producer but its milk has a high average butterfat content (between 4% and 5%). As it is best suited, of the dairy goat breeds, to hot conditions, the Anglo-Nubian has been used in grading up programs in many tropical countries to increase the milk and meat production of local breeds. The Anglo-Nubian is a relatively large, proud, and graceful dairy goat. It is named after Nubia, in northeastern Africa. The original goats imported from Africa, Arabia, and India were long legged, hardy goats that had some characteristics desired by goat breeders in England. English breeders crossed these imported bucks on the common short-haired does of England before 1895 to develop the Anglo-Nubian goat. In the United States, the breed is usually spoken of as the Nubian. The Anglo-Nubian is regarded as an aristocratic-appearing goat and has very long, pendulous ears that hang close to the head. It carries a decidedly Roman nose and is always short haired. Any solid or parti-colored coat is permitted in the Anglo-Nubian, but black, red, or tan are the most common colors, any of which may be carried on combination with white. Usually there is shorter hair on the Anglo-Nubian males, particularly along the back and on the thigh, than is commonly found on the Swiss breeds. Its udder is capacious but is sometimes more pendulous than that of the Swiss breeds. A mature doe should stand at least 30 in. at the withers and weigh 135 lbs or more, whereas the males should stand at least 35 in. at the withers and weigh at least 175 lbs. It usually gives less milk than the Swiss breeds but produces a milk of higher butterfat content. The head is the distinctive breed characteristic, with the facial profile between the eyes and the muzzle being strongly convex. The ears are long (extending at least 1 in. beyond the muzzle when held flat along the face), wide, and pendulous. They lie close to the head at the temple and flare slightly out and well forward at the rounded tip, forming a 'bell' shape. The ears are not thick, with the cartilage well defined. The hair is short, fine, and glossy (Briggs and Briggs, 1980; Mason, 1988; Meat and Livestock Australia, 1989; American Dairy Goat Association, n.d.).

Meat goats

Black Bengal

The Black Bengal goat is a breed of goat found in West Bengal, Bihar, and Odisha regions of northeastern India and

throughout Bangladesh. This breed is usually colored black, but it is also found in brown white or gray. The Black Bengal goat is small in size. Its body structure is tight. Its horns are small and legs are short. Adult male goat weights approximately 25–30 kg and female 20–25 kg. It is poor in milk production. It is very popular in Bangladesh because of its very low demand of food and very high reproduction rate. The Black Bengal goats gain sexual maturity very early. The female goat conceives twice a year and gives birth to 2–3 baby goats every time. This breed can adapt to any environment easily and its disease-preventive ability is very high. It produces high-quality meat and skin. This breed plays a very important role in reducing unemployment and poverty from Bangladesh (Mason, 1996).

Fiber goat

Angora

The Angora goat originated in the district of Angora in Asia Minor. The Angora dates back before early Biblical history. Mention is made of the use of mohair at the time of Moses, which would fix the record of the Angora sometime between 1571 and 1451 BC, according to the Angora Goat Mohair Industry publication from the United States Department of Agriculture. Mohair became a valuable product in commerce early in the nineteenth century. To increase the supply of mohair available for export to the European countries, the Turks crossed the Angora goat with common stock to increase the poundage of salable hair. Probably there was no effort to keep the original Angora separate, and the general increase in size and vigor of the goats in the Angora area was, undoubtedly, partially the result of this infusion of other blood. Angora stock was distributed to different countries, and a pair of Angoras was imported to Europe by Charles V around 1554.

Mohair production – The most valuable characteristic of the Angora as compared with other goats is the value of the mohair that is clipped. The average goat in the US shears approximately 5.3 lbs of mohair per shearing and is usually sheared twice a year. They produce a fiber with a staple length between 12 and 15 cm. The mohair is very similar to wool in chemical composition but differs from wool in that it has a much smoother surface and very thin, smooth scale. Consequently, mohair lacks the felting properties of wool. Mohair is very similar to coarse wool in the size of fiber. It is a strong fiber that is elastic, has considerable luster, and takes dye very well. Mohair has been considered very valuable as an upholstering material for the making of plushes and other covering materials where strength, beauty, and durability are desired (Briggs, 1969; Select Genes Ltd., 1675; Meat and Livestock Australia, 1989).

Systems of goat production

The systems in which people keep goats differ from country to country. There are three main systems of production, viz., (1) extensive grazing, (2) sedentary family herds, and (3) intensive commercial production.

Housing management

- Goats are housed in stalls or loose boxes. For efficient production in dairy goats, the animals must be provided with good health and comfort. The house should protect goats from the sun, rain, and cold nights. One need not have expensive house for the goats. Instead, locally available material can be used. A mature goat requires $1.5 \times 1.0\ m^2$ floor space. To protect the goats from cold air, especially at night and rainy days, a wall of at least 1.5 m or 4.2 ft height should be built. If the floor is made of clay or earth, it should be compact, as far as possible, and there should be a gradual slope toward one corner of the house. If the floor is made of wood, it should be elevated and slated with just at least 0.5–0.75 in. space in between to facilitate easy escape of manure and urine.
- Bucks should be housed far away from the dairy goat shed. This will help in avoiding goat's smell in the milk. Kids up to 2 weeks of age should be kept with the does.
- The stalls may be arranged in two rows, with a passage between them. The recommended dimensions on each stall should be 0.75 m wide and 1.05 m long. The length of the shed will depend on the number of milch goats kept. There should be portions between stalls made of brick, stone, or iron tubing. Sometimes a small milk room is constructed at one end of the milch goat shed, especially in breeding farms.
- The methods commonly used to control the goats are herding, tethering, and fencing. Control methods help to prevent the loss of goats by theft, attacks from wild animals, or by the goats wandering off. Also, they limit the amount of feed that goats have access to at any time and prevent damage to crops.

Feeds and Feeding

Feed represents the highest item of expenses in raising goats; hence, it is very necessary to understand the principles of feeding in order to feed goats economically. A nutrient is a substance that aids in support of life. Goats require nutrients for growth, body maintenance, pregnancy or reproduction, and milk production. Nutrients required in the goat's feed are energy, protein, minerals, vitamins, and water.

Goat is a ruminant, but its feeding is quite dissimilar from that of sheep and cows. For its size, a goat can consume substantially more feed than cow or sheep, which can be 6.5–11% of its body weight in dry matter compared with 2.5–3.0% in case of cattle and sheep. This means that goats can satisfy their maintenance and production requirement on good fodder and pasture grass.

- Concentrates: These are low in crude fiber and high in digestible nutrients. Concentrates low in protein are maize, rice, sorghum, bran, molasses, etc., whereas protein-rich concentrates are groundnut cake, cottonseed cake, soyabean meal, etc.
- Roughage: These are high in crude fiber but low in digestible nutrients, such as sorghum fodder, bajra fodder, rice and wheat straw, grasses like paragrass and young pasture grasses, silage, and dry hay.
- Feed additives: There are chemicals that are added to feed for growth promotion or for disease prevention, for example, antibiotics aureomycin, and terramycin.
- Minerals: Salt, oyster shell, lime stone, bone meal, wood ash, etc. supply minerals to goat's body.

- Vitamins: Dietary requirements of goats are simple because feeds that they consume mostly supply their necessary requirements.
- Local ingredients used in goat feed: These high-energy ingredients are rich in fat and proteins. Maize, sorghum, wheat bran, rice bran, groundnut cake, cottonseed cake, by-products of legumes, molasses, etc. are important goat feed.

Feeding the goat

Goats are fed differently depending on whether they are dry, pregnant, lactating, breeding, buck, or baby goat.

- Feeding the dry doe – Feed well during the pregnancy as the unborn babies gain more weight during the last week of pregnancy. The pregnant doe should be in good flesh and weight before giving birth. Nutritious grasses and legumes are sufficient to support the doe. If the pregnant doe looks thin then give approximately 0.5–1 kg of concentrate mixture.
- Feeding the doe about to kid – 3–5 days before giving birth, give pregnant doe approximately 250–500 g of concentrate. Then 1–2 days before kidding, replace this concentrate ration with just maize, bran, wheat bran, or rice bran. The bran is known for its laxative property and will help to clean the stomach. Clean stomach will assist the doe in easy kidding.
- Feeding the milking doe – Milk does should be given as much quality grasses and legumes as they can consume. Concentrate grams for every liter of milk should be given and fresh water and mineral lick-brick should be provided to the does frequently.
- Feeding the bucks – Bucks used for breeding should be fed properly. When not used for breeding, feed a buck at least 500 g of concentrate mixture plus green grass and legume, like lucerne. See that the does do not become fat, aggressive, and sterile. During breeding period, increase its ration from 500 g to 1 kg.
- Feeding young kids – The object should be not to fatten them up but rather provide them enough nutrients for growth and maintenance. Sufficient space for exercise plus abundant quality grass and legumes are important for yearlings. Feed 500 g of concentrate every day.
- Feeding the baby goats – Keep the kids with the mother for the first 2–3 days. This will ensure sufficient intake of colostrum needed for their good health. From the 3rd or 4th day, allow the kid to be with the mother only during the day. Continue this up to 4–5 months, i.e., till they are weaned. You can feed the kid with the help of a bottle. For this you must separate the kid from the doe after the 3rd or 4th day of its birth. Take care to keep the milk warm around 103–105 °F. Keep the nipple and bottle clean after each feeding.

Goat's Population

In the year 2011, there were 875.53 million goats in the world.

Goat Milk Production

Aggregate (official, semiofficial, or estimated data) of 15.85 million tons goat milk was produced throughout the world in the year 2011.

Goat Meat Production

In the year 2011, world's aggregate goat meat production was 5 114 494 tons.

Goatskin Production

Aggregate 1 138 100 tons goatskin was produced throughout the world in the year 2011.

Sheep

Animal belonging to the phylum Chordata (backbone animals), class Mammalia (milk giving), order Artiodactyla (even toed and hoofed), suborder Ruminatia (cud-chewing), family Bovidae (hollow unbranched horn), and genus *Ovis* is sheep.

Zoological Classification of Sheep

Table 15 explains the zoological classification of sheep.

Domestication of Sheep

An archeological site in Iran produced a statuette of a wooled sheep, which suggests that selection for woolly sheep had begun to occur more than 6000 years ago. The common features of today's sheep already appeared in Mesopotamian and Babylonian art and books by 3000 BC.

Number of chromosome pairs of sheep: 54 (*Ovis aries*).

Body Weights

Body weight in sheep ranges from 2.0–4.0 kg at birth to 34–80 kg at maturity.

Common Terms Related to Sheep

Terms related to sheep that are commonly used are given in Table 16.

Utility

Milk, meat, fleece, manure, and hide.

Important Breeds of Sheep

Selection for wool type, flocking instinct, and other economically important traits over the centuries has resulted in more than 200 distinct breeds of sheep occurring worldwide.

Table 15 Zoological classification of sheep

Kingdom	Animalia
Phylum	Chordata (backbone animals)
Class	Mammalia (milk-giving)
Order	Artiodactyla (even toed and hoofed)
Suborder	Ruminatia (cud-chewing)
Family	Bovidae (hollow unbranched horn)
Genus	*Ovis*
Species	*Ovis aries* (sheep)

Table 16 Common terms related to sheep

Common name of animal	*Male*	*Female*	*Young*	*Group*	*Act of mating*	*Gestation/pregnancy period*	*Name of giving birth*
Sheep	Buck/ram	Ewe/dam	Lamb	Flock	Tupping	148–156 days	Lambing

Modern breeding schemes have also resulted in an increasing number of composite or synthetic breeds that are the result of a crossing of two or more established breeds.

Sheep can be grouped into two breed groups as hair-sheep breeds and Merino sheep types.

Hair-sheep breeds – Africana, Barbado, Barbados Blackbelly, Blackhead Persian, Brazilian Somali, Damara, Dorper, Katahdin, Masai, Morada Nova, Pelibuey, Rabo Largo, Sahel type, Somali, St. Croix (Virgin Island White), Touabire, Uda, West African Dwarf, and Wiltshire Horn.

Merino sheep types – Booroola Merino, Delaine Merino, Fonthill Merino, German Mutton Merino, Medium-Wool Merino, Merinolandschaf, Poll Merino, South African Merino, South African Mutton Merino, and Strong Wool Merino.

Sheep Population

In the year 2011, there were 1 043 712 633 sheep in the world.

Sheep Milk Production

Aggregate (official, semiofficial, or estimated data) of 9.26 million tons sheep milk was produced throughout the world in the year 2011.

Sheep Meat Production

In the year 2011, world's aggregate sheep meat production was 7 911 505 tons.

Sheeepskin Production

Aggregate 1 741 333 tons sheepskin was produced throughout the world in the year 2011.

Wool Production

1 985 797 tons of wool (greasy) was produced throughout the world in the year 2011.

Detection and Causes of Bovine Mastitis with Emphasis on *Staphylococcus aureus*

KL Anderson and RO Azizoglu, North Carolina State University, Raleigh, NC, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Bovine Cattle or closely related ruminants.
Enterotoxins Toxins elaborated by some strains of *Staphylococcus aureus* that may cause gastrointestinal signs (vomiting, diarrhea, etc.) when ingested by a person.
Mastitis Inflammation of the mammary gland, usually caused by microorganisms infecting the gland.
Methicillin-resistant *Staphylococcus aureus* Bacterium that is resistant to the antibiotic methicillin, and that can cause serious infections in man and animals.
Pathogenic Disease producing.
Staphylococcus aureus Bacterium that causes mastitis in cattle and other diseases in a number of species.

General Summary of Mastitis

Bovine mastitis is the leading cause of economic losses in the dairy industry worldwide, primarily due to a decrease in the quantity and quality of milk. Expenses associated with the treatment of mastitis, such as use of antimicrobials and the requirement of discarding the milk from treated cows during the withhold period, cause additional economic losses to dairy farmers (Barkema *et al.*, 2009). Annual mastitis losses in the United States are estimated at more than US$2 billion by the National Mastitis Council (Hogan *et al.*, 2011). Mastitis also negatively impacts cow health and reproductive performance.

Mastitis is almost always caused by the entry of pathogenic bacteria through the opening at the end of the teat, the teat duct, causing inflammation of the mammary glands (Schalm *et al.*, 1971, p. 1). Bovine mastitis can be caused by a wide variety of pathogenic microorganisms. Some mastitis specialists divide mastitis microorganisms into major or minor pathogens, relative to the degree of inflammation and seriousness of the signs they cause. Major pathogens are those that produce more serious disease and inflammation. Minor mastitis-causing microorganisms cause only a slight amount of irritation and uncommonly produce clinical mastitis.

Microorganisms that most mastitis specialists consider as major pathogens include, among others:

- *Staphylococcus aureus*
- *Streptococcus* spp. (*Streptococcus agalactiae*, *Streptococcus dysgalactiae*, *Streptococcus uberis*, etc.)
- *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*)
- *Mycoplasma* spp.
- *Escherichia coli*
- *Klebsiella* spp.

Minor mastitis-causing pathogens are commonly considered to include:

- Various species of coagulase-negative *Staphylococcus* spp.
- *Corynebacterium* spp.

Many of these mastitis-causing pathogens and other possible mastitis-causing microorganisms can be present in the dairy environment and can pose a threat to dairy cows. Therefore, mastitis control strategies have been developed to control and minimize the risk of mastitis on a dairy farm. The most commonly recognized mastitis control program consists of a five-point program to control mastitis pathogens on a dairy farm. In this program, suggested measures recommended to control a pathogen such as *S. aureus* include establishing proper milking techniques for prevention of new infections, using individual towels for udder cleaning, and postmilking teat disinfection. Two measures for elimination of intramammary infections include using antimicrobial therapy or culling of the cow, depending on the severity of the case (Bramley and Dodd, 1984; Sommerhäuser *et al.*, 2003).

In accordance with this recommended mastitis control program, mastitis is the main reason for use of antimicrobials, particularly antibiotics, in the dairy industry. As a result of extensive use of antimicrobials in both human and veterinary medicine, the emergence of antimicrobial-resistant organisms has become an important public health concern. Early detection of mastitis is becoming more important in order to minimize the use of antimicrobials in mastitis cases. This may limit the damage to the mammary glands caused by the infectious agent, as well as increase the success of treatment.

Mastitis cases are classified as subclinical, clinical, or chronic. Subclinical mastitis can be the early stage of a mastitis case and there are no visible changes in the milk or the cow's mammary gland. Diagnosis of mastitis at the subclinical stage may significantly improve treatment success and limit damage to the mammary glands. In clinical mastitis cases, there is inflammation and damage in the mammary glands and the udder is often swollen. Chronic mastitis is the persistence of the infectious agent in the udder, often at the subclinical stage. In contagious mastitis, measures such as segregation of the cow and intramammary antibiotic treatment of the udder may limit the spread of infectious agents to other cows.

Mastitis Detection Tests

Timely detection of a mastitis case may significantly improve the success of treatment and limit the losses associated with mastitis. Therefore, in the dairy industry there are several

methods that are used for early detection of mastitis. A dairy farm could implement one or more of the following detection tests, depending on the particular farm's management decisions.

1. *Determination of total somatic cell counts in milk*: Enumeration of somatic cells in milk and evaluation relative to critical thresholds is used in the diagnosis of bovine mastitis. In the course of mastitis, the presence of pathogenic organisms in the gland triggers an immune response from dairy cows, producing increases in the number of somatic cells in milk (Olechnowicz and Jaśkowski, 2012; Jayarao *et al.*, 2004; Lievaart *et al.*, 2007; Pantoja *et al.*, 2009). Previous studies characterizing differential milk somatic cell profiles of healthy cows reported varying percentages of each cell type. However, the reports agreed on the specific cell types present in milk (Pilla *et al.*, 2012; Schwarz *et al.*, 2011; Koess and Hamann, 2008; Merle *et al.*, 2007; Sarikaya *et al.*, 2006; Dosogne *et al.*, 2003; Rivas *et al.*, 2001; Leitner *et al.*, 2000). Cells present in cow milk include polymorphonuclear leukocytes, lymphocytes, and macrophages. On infection of the mammary glands, dramatic increases in milk cells occur by transfer of white blood cells from blood to the mammary glands (Kelly *et al.*, 2000; Olechnowicz and Jaśkowski, 2012). The primary cells that transfer from the blood stream are the polymorphonuclear leukocytes, and their level increases up to 90% of the total somatic cells (Olechnowicz and Jaśkowski, 2012). This increase in milk total somatic cell numbers during intramammary infection is commonly used as a diagnostic and quality evaluation tool in the dairy industry. It was previously reported that the increased somatic cell numbers in milk cause changes in milk composition, especially reductions in lactose, fat, and casein content (Kelly *et al.*, 2000; Lindmark-Mānsson *et al.*, 2006). Although determination of total somatic cell count provides useful information in determining possible presence of a mastitis case, further characterization of the infectious agent may be required to implement effective treatment of the mastitis case.
2. *California mastitis test* (*CMT*): The CMT is a very widely used onsite test in the dairy industry. This test was developed to estimate the total somatic cell count by using an anionic detergent (Schalm *et al.*, 1971, p. 12). The detergent is mixed with the milk sample and the milk thickens if the somatic cell count of the sample is high. Mastitis is diagnosed by qualitative scoring of the thickening of the milk sample. The test is commonly used because it is a simple, inexpensive test and does not require extensive training of the personnel. However, this test is quite subjective as the evaluation of the change is analyzed by personnel and also further characterization of the possible mastitis case may need to be implemented to select the effective treatment.
3. *Measurement of electrical conductivity of milk*: Mastitis, i.e., inflammation of the mammary glands, causes changes in the composition of milk. As a result of transfer of white blood cells from bloodstream to the mammary glands, the concentrations of Na^+ and Cl^- increase and lactose and K^+ decrease in milk (Kitchen, 1981; Oshima, 1977; Nielen *et al.*, 1992). This changed concentration of Na^+, Cl^-, and K^+ produces increases in the electrical conductivity of mastitic milk (Kitchen, 1981; Nielen *et al.*, 1992). Using available tools for measuring electrical conductivity, the potential occurrence of intramammary infection can be detected. However, similar to above mentioned methods, measurement of electrical conductivity only provides information about the presence of mastitis but not about the specific infectious agent. Therefore, further characterization is required to select the effective intervention for treatment.
4. *Standard microbiological culturing of milk samples*: Standard microbiological culturing of milk samples is widely accepted as the 'gold standard' for diagnosis of intramammary infections in the dairy industry. This method involves enrichment of the pathogenic organism from the aseptically collected milk sample from the infected quarter. As this method enables identification of the specific agent that causes the mastitis case, it is possible to employ the most effective treatment method. Although this method enables specific identification of a mastitis case, it is used less commonly for routine screening of a dairy herd as it requires highly trained personnel, it takes time to grow organisms (at least 24 h), and the samples are prone to contamination during aseptic collection. In addition, there are reported mastitis cases in which microbiological cultures give negative results. Reasons for false negative results include, among others, special growth requirement of some mastitis-causing organisms (e.g., *Mycoplasma* spp.), the state of the mastitis-causing organism (e.g., organism might be in viable-but-nonculturable state), and instances where the inflammatory reaction is still present but the microbes have been cleared.
5. *Application of real-time polymerase chain reaction* (*RT-PCR*): With the advancement of molecular diagnostic techniques, commercial diagnostic kits using RT-PCR have become available for detection of mastitis pathogens. This method enables detection of species-specific regions of the deoxyribonucleic acid (DNA) of pathogenic organisms, yielding a highly sensitive and specific tool for detection of a mastitis case. Previous studies reported high accuracy of this method compared to bacterial culture method (Koskinen *et al.*, 2010). The biggest disadvantage of this method is that the test needs to be conducted using highly technical equipment by trained personnel. In addition, although the commercial kit is able to detect majority of mastitis-causing organisms, if mastitis is caused by an uncommon organism this method would give false negative results.

Methicillin-Resistant *Staphylococcus aureus*, Prevalence in Dairy Industry, and Food Safety Implications of *Staphylococcus aureus* in Milk

Antimicrobials such as penicillin and cephalosporins are used in the dairy industry for treatment or prevention of mastitis and other diseases caused by bacterial organisms. The multistate surveillance report issued by US Department of Agriculture National Animal Health Monitoring system indicated that mastitis was the most common disease in the dairy industry associated with antibiotic use in 2007 and 2002 (in 2007 16.4% and in 2002 15.0% of cows were treated for mastitis) (**Figure 1**; USDA APHIS, 2008). The primary

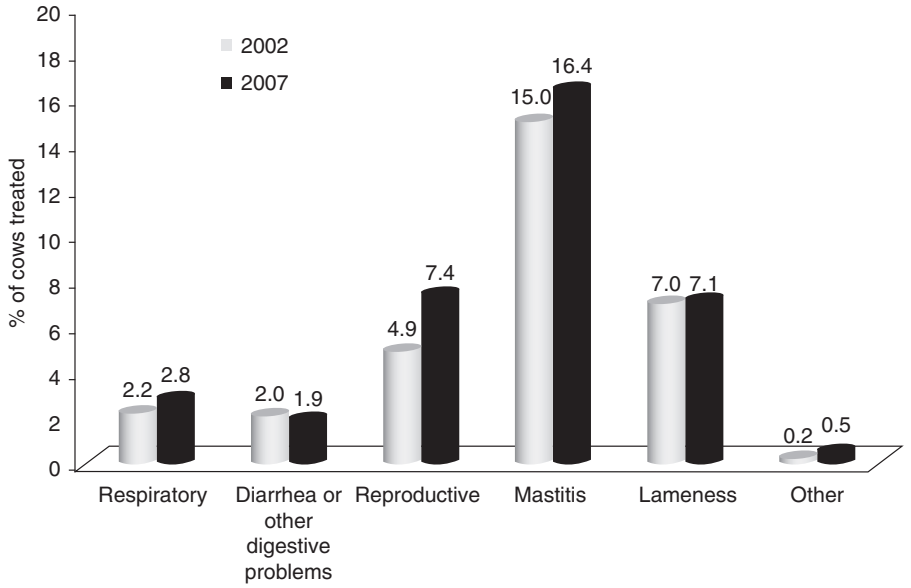

Figure 1 Use of antibiotics at dairy farms in the United States during the previous 12 months of 2002 and 2007. Reproduced from United States Department of Agriculture, Animal Plant Health Inspection Service National Animal Health Monitoring System (USDA APHIS, 2008). Antibiotic use on U.S. dairy operations, 2002 and 2007. Available at: http://www.aphis.usda.gov/animal_health/nahms/dairy/downloads/dairy07/Dairy07_is_AntibioticUse.pdf (accessed 05.05.13).

antibiotic class used for mastitis treatment was cephalosporins (53.2% in 2007 and 36.8% in 2002), followed by lincosamide (19.4%) in 2007 and noncephalosporin beta-lactams (33.8%) in 2002 (**Figure 2**; USDA APHIS, 2008). In addition to treatment, use of antimicrobials as a mastitis preventive measure during the nonlactating period improves the health and productivity of dairy cows, and reduces mastitis incidence. Therefore, some dairy farms use 'dry cow' therapy, in which approved antimicrobials are administered to all quarters of all cows in the herd at the end of lactation (dry-off) (Oliver and Murinda, 2012). It is known that extensive use of antimicrobials serves as a selective pressure for antimicrobial-resistant strains of bacteria (Piddock, 1996). Epidemiological studies on *S. aureus* have revealed that a limited number of isolates persisted in individual herds. These genotypes may have developed necessary resistance or virulence mechanisms, or other properties, that allowed them to persist in cows on specific dairy farms (Anderson and Lyman, 2006; Matthews *et al.*, 1994; Sommerhäuser *et al.*, 2003). The antimicrobials used in veterinary medicine often differ from the antimicrobials used in human medicine. However, the development of resistance to a certain group of antimicrobials could lead to cross-resistance of an organism to other antimicrobials, including those possibly used in human medicine (Piddock, 1996). Therefore, the prevalence of antimicrobial-resistant microorganisms in farm animals and their environment is considered by some to be an important public health consideration. In this respect, one report from an organization focused on the dairy industry and milk quality has concluded that "Scientific evidence does not support a widespread emerging resistance among mastitis pathogens to antibacterial drugs" (Erskine *et al.*, 2004).

Staphylococcus aureus is a Gram-positive bacterium that is considered as one of the major mastitis-causing pathogens. *Staphylococcus aureus* is commonly associated with subclinical, clinical, or chronic mastitis in the dairy industry (Barkema *et al.*, 2009). As *S. aureus* has the ability to spread within and among cows during milking, it is considered as a contagious udder pathogen (Barkema *et al.*, 2009; Capurro *et al.*, 2010). Therefore, accurate and reliable detection of *S. aureus* is crucial for control of the organism in a dairy herd. In routine clinical testing, *S. aureus* is usually differentiated from other less pathogenic members of the *Staphylococcus* genus by its hemolytic and coagulase activities (Boerlin *et al.*, 2003). Although previous studies characterizing the antimicrobial susceptibility of mastitis-associated *S. aureus* isolates reported low number of antimicrobial-resistant *S. aureus*, some level of antimicrobial resistance has been observed (Erskine *et al.*, 2002; Owens and Watts, 1988; Anderson *et al.*, 2006).

Staphylococcus aureus isolates that phenotypically possess resistance to methicillin and related beta-lactam antibiotics are classified as methicillin-resistant *Staphylococcus aureus* (MRSA) (Shore *et al.*, 2011). Since first reported in 1961 in England (Jevons, 1961), MRSA has become a major public health concern as a significant antibiotic resistant pathogen in hospitals, primarily through nosocomial infections (Aquino *et al.*, 2012; Shore *et al.*, 2011). MRSA isolates are often resistant to other drugs (multidrug resistant) as well and this results in increased treatment time and costs, as well as higher hospitalization rates (Haran *et al.*, 2012; Cosgrove, 2006; Noskin *et al.*, 2005). Parallel to its significance in human medicine, awareness of MRSA is increasing in veterinary medicine because of its zoonotic potential (Shore *et al.*, 2011). The first MRSA strain from a dairy cow was isolated in 1972 (Devriese *et al.*, 1972). Although since then there are reports of sporadic MRSA isolation from mastitis cases in dairy cattle, the prevalence of MRSA is typically very, very low among *S. aureus* isolates from bovine mastitis cases (Ferreira *et al.*, 2012; Fessler

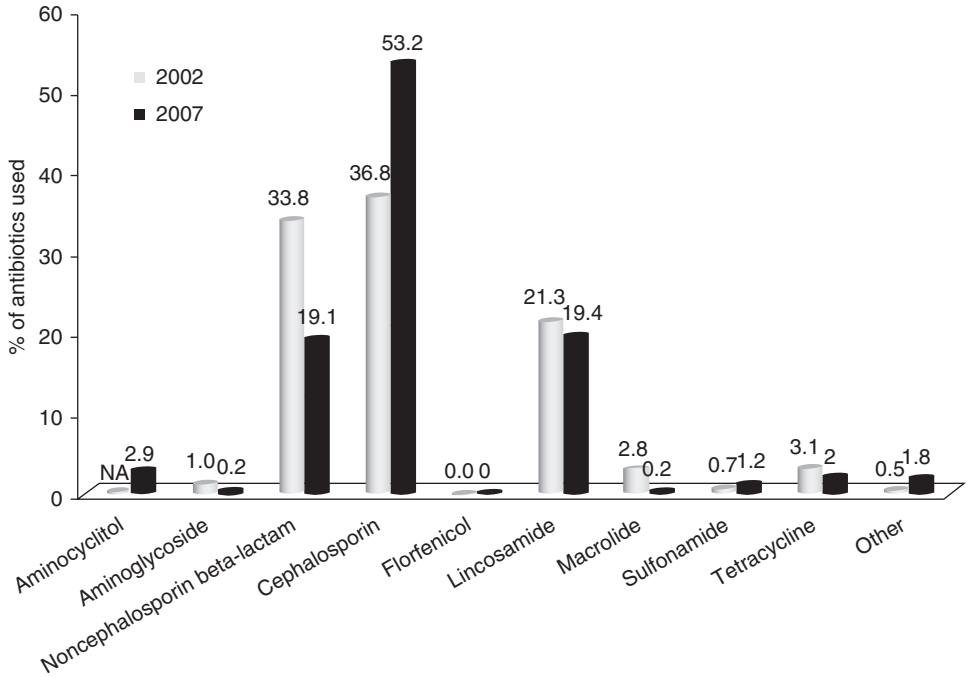

Figure 2 Percentage of primary antibiotic used for treatment of cows during the previous 12 months of 2002 and 2007. Reproduced from the data presented in USDA APHIS United States Department of Agriculture, Animal Plant Health Inspection Service National Animal Health Monitoring System, 2008. Antibiotic use on U.S. dairy operations, 2002 and 2007. Available at: http://www.aphis.usda.gov/animal_health/nahms/dairy/downloads/dairy07/Dairy07_is_AntibioticUse.pdf (accessed 05.05.13).

et al., 2010; Huber *et al.*, 2009; Juhász-Kaszanyitzky *et al.*, 2007; Vanderhaeghen *et al.*, 2010; Weese, 2010). Two recent surveys found no MRSA in bulk tank milk samples in the United States, but there are reported MRSA isolations from dairy in other parts of the world (Ferreira *et al.*, 2012; Virgin *et al.*, 2009). Some MRSA isolates found in livestock are referred as 'livestock-associated MRSA' (LA-MRSA). Some authors report that these MRSA isolates do not commonly colonize in human hosts (Köck *et al.*, 2013). However, there are reports of LA-MRSA passing the species barrier and colonizing the nasopharynx of pig farmers and veterinarians (Cuny *et al.*, 2009; Köck *et al.*, 2012; Köck *et al.*, 2013; Wulf *et al.*, 2008). LA-MRSA isolates are usually colonized in pigs and the reports of dairy isolates of MRSA can be from small-scale, multispecies farm environments. This suggests that the MRSA isolates can be transmitted from other farm animals to dairy cattle.

In the majority of MRSA isolates, resistance is the result of harboring the *mecA* gene that encodes altered penicillin binding protein (PBP2a or PBP2′). This protein has low affinity for beta-lactam antimicrobials (such as cephalosporins, etc.) (Weese, 2010). A large mobile genetic element, the staphylococcal cassette chromosome *mec* (SCCmec), carries the *mecA* gene along with a set of recombinase genes (*ccrA*, *ccrB*, or *ccrC*) for restriction and integration into the host chromosome (Graveland *et al.*, 2011). This SCCmec can be localized on a specific site in the chromosome of a methicillin-susceptible *S. aureus*. Recently, MRSA isolates that are lacking the *mecA* gene have also been reported (Shore *et al.*, 2011; García-Álvarez *et al.*, 2011).

Food Safety Implications of *Staphylococcus aureus* in Milk

Staphylococcus aureus is considered as a foodborne pathogen because it can produce heat-stable enterotoxins during its growth in foods and these enterotoxins can cause food poisoning in humans and animals (Marrack and Kappler, 1990). It is estimated that annually approximately 241 000 persons in the United States experience food poisoning due to staphylococcal enterotoxins (Doyle *et al.*, 2012; Scallan *et al.*, 2011). The food poisoning associated with staphylococcal enterotoxin occurs very shortly after ingestion of the causative food (can start within 3 h of ingestion) and includes signs of abdominal pain, nausea, and vomiting. Dairy foods are among the food categories that are responsible for food poisoning cases associated with staphylococcal enterotoxins (2.1% of the reported 573 outbreaks in the United States between 1998–2010) (Doyle *et al.*, 2012). One of the largest staphylococcal intoxication cases occurred in Japan in 2000 and was associated with low fat milk and more than 13 000 cases were reported (Asao *et al.*, 2003; Doyle *et al.*, 2012). Another staphylococcal intoxication outbreak occurred in 2007 in Paraguay. This outbreak affected approximately 400 individuals and was associated with ultrapasteurized milk product (Doyle *et al.*, 2012). Pasteurization of milk is a common practice in the dairy industry, and pasteurization would result in viable *S. aureus* being eliminated from the product. However, the staphylococcal enterotoxins would resist destruction by the high temperatures of pasteurization and would be present in the final food product. Therefore, staphylococcal

enterotoxins pose a food safety concern as in the foodborne staphylococcal intoxication outbreak in Paraguay in 2007.

The prevalence of MRSA in the dairy industry is low. However, MRSA is a potential food safety concern for dairy products that are made from unpasteurized milk. As of 2012, it was reported that there was no report of MRSA cases associated with a dairy food contaminated with the organism (Doyle *et al.*, 2012). At the time of this writing, only two cases of foodborne MRSA outbreaks were reported, both of which were associated with contamination of food materials by the food handlers (Jones *et al.*, 2002; Kluytmans *et al.*, 1995).

Glossary

Gangliosides Glycolipids with negatively charged glycans containing one or more sialic acid residues.
Glycoconjugate Molecule in which one or more glycan units are covalently linked to a noncarbohydrate entity (e.g., protein or lipid).
Glycolipids Lipids with one or more glycans attached.
Glycoprotein Protein with one or more covalently bound glycans.
Mass spectrometry Analytical technique that measures the charge-to-mass-ratios of molecules.
Oligosaccharides Carbohydrates consisting of between 2 and 20 monosaccharides, linear or branched connected by either an α- or β-glycosidic linkages. May also be referred to as glycans, especially when attached to other noncarbohydrate structures like proteins and lipids.
Peptide A fragment of a protein released by enzymatic cleavage.
Prebiotics Selectively fermented ingredients that allow specific changes, both in the composition and activity in the gastrointestinal microbiome that confers benefits on host's well-being and health.
Recovery The amount of pure extracted compounds that can be recovered from a matrix.
Whey Liquid part of milk that separates from the curds during cheese-making.

Guiding Agriculture, Food, and Nutrition Sciences to Improve the Sustainability and Health Value of the Food Supply System

During the twentieth century, nutrition science advanced by identifying and characterizing nutrients essential for growth and development. At the same time, food production and processing advanced largely as commodity-driven enterprises benefiting from engineering and science techniques that enabled unprecedented economies of scale. Food fortification and enrichment efforts in developed countries have since eliminated many nutritional deficiencies that previously plagued humanity. These efforts, combined with population-based approaches also had the unfortunate consequence of begetting an era of overnutrition, obesity, and increased environmental degradation. These economies of scale also produce waste at unprecedented levels. The food and beverage industries alone produce approximately 3.5 billion tons of agricultural residues yearly in the world (John, 2009). Designing systems that deliver individually appropriate food and nutrition solutions through efficient utilization of renewable resources will be a hallmark of industrial development in the new millennium.

Currently, most organic waste streams have potential for reutilization, as they contain components valuable for health improvement. Recent evidence suggests that many of the same biomolecules in food processing waste streams that contribute to environmental damage, are also biologically active, health-promoting molecules (Wijngaard *et al.*, 2012). Till date, these 'waste' streams remain relatively untapped resources waiting to be exploited for valuable, healthy components, with concomitant mitigation of environmental damage.

Advances in high-throughput analytical methods, novel scale-up processing methods, and 'big data' information systems, provide a platform of technologies on which agriculture, food, and nutrition sciences can address these large-scale environmental and societal health problems. Biology and biochemical sciences are proceeding rapidly in the identification of structure-interaction-function relationships that bring to light precise molecular targets and biochemical mechanisms underlying various health and disease processes and endpoints. Identifying these mechanisms of health and disease processes provides biomolecular intervention targets. At the same time, the molecular decomposition of food commodities and processing streams is producing libraries of source materials for bioactive chemicals, and the underlying biological and processing conditions that give rise to their formation.

Figure 1 illustrates a life-cycle diagram for the development of new functional ingredients. First (1) desired optimal physiologic conditions are identified, and associated with related biological processes and biochemical pathways, leading to the development (2) of health targets. Provisioning of health targets enables (3), the identification of potential bioactive mediators. Lab separation techniques can deconstruct foods and their processing effluents to reveal classes of contained bioactive molecules (4). Utilizing advanced instrumentation and analysis techniques, these classes of molecules can then be further characterized and quantified (5) to the molecular level. Lab-scale quantities of these molecules can be made available (6) for *in vitro* and *in vivo* experiments that validate target and molecule selection choices. Quantitation of these molecules within foods and food byproducts (7) permits the development of pilot-scale separation techniques. When these techniques are scaled up to industrial levels (8), they can be leveraged to reduce pollution in food processing effluents while providing functional ingredients for new food products (9) for population health improvement.

The remainder of this article follows four classes of bioactive molecules through case studies along the functional food

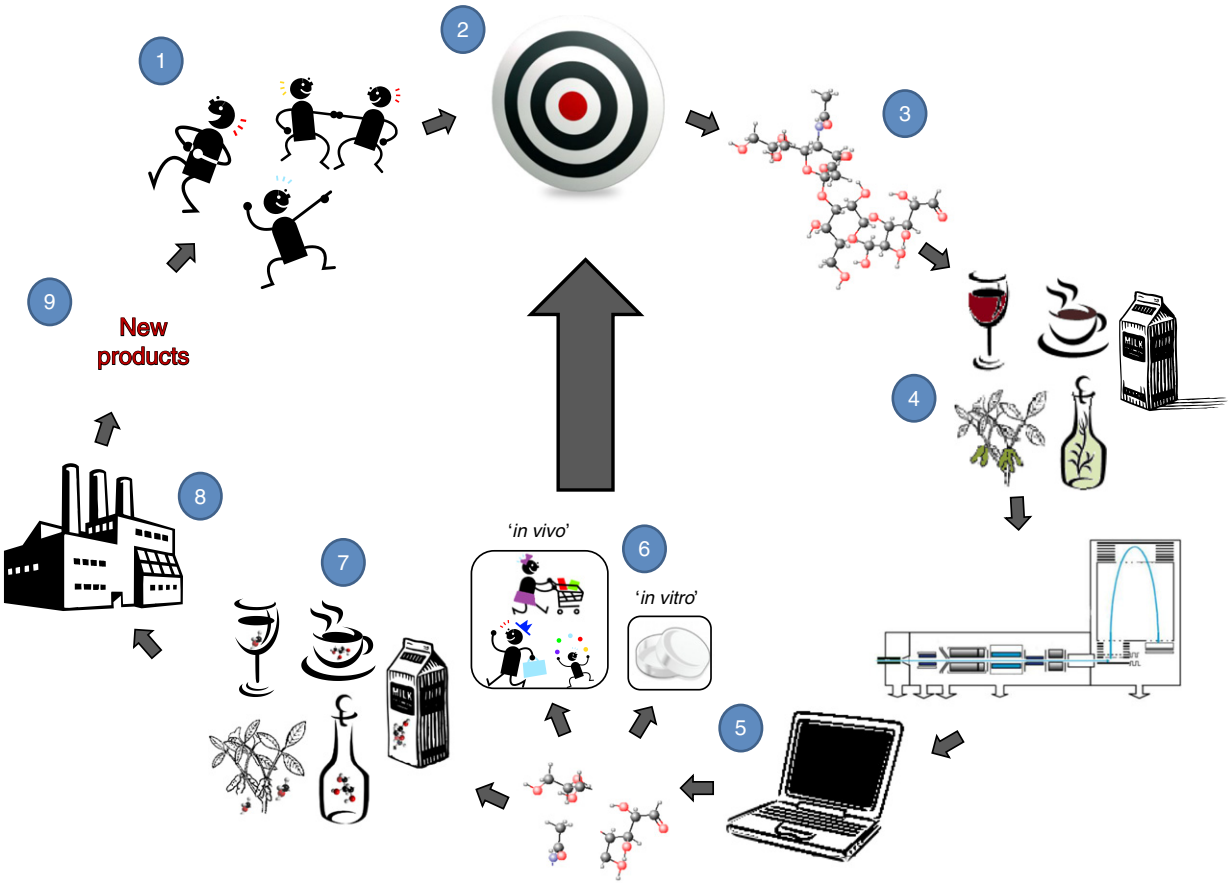

Figure 1 Functional ingredient development life cycle: (1) desired optimal physiological conditions are identified and associated with related biological processes and biochemical pathways; (2) development of health targets; (3) provisioning of health targets enables the identification of potential bioactive mediators; (4) lab separation techniques can deconstruct foods and their processing effluents to reveal classes of contained bioactive molecules; (5) utilizing advanced instrumentation and analysis techniques, these classes of molecules can then be further characterized and quantified to the molecular level; (6) lab-scale quantities of these molecules can be made available for *in vitro* and *in vivo* experiments that validate target and molecule selection choices; (7) quantitation of these molecules within foods and food by products permits the development of pilot-scale separation techniques; (8) when these techniques are scaled up to industrial levels, they can be leveraged to reduce pollution in food processing effluents while providing functional ingredients for new food products; and (9) population health improvement.

development life cycle. Beginning with health and food target endpoints, the reader then progresses through scientific and engineering components of functional bioactive molecule identification and recovery from foods and food processing effluents, to arrive at the exploration and validation of effects these molecules have in individuals, and their potential manipulation to enhance future product development.

Bioactive Molecules versus Nutrients

Nutrients are defined as molecules that are essential for human health. Bioactive or functional molecules have not been shown to be essential for human health, but have the capacity to modulate biological processes that confer health. In this article, 'bioactive' and 'functional' refer to these health-improving molecular properties. Many nonnutrient, bioactive constituents of animal, edible plant, and edible fungi foods have been investigated and annotated for functional molecules with positive health benefits when ingested. Databases that record evidence of health-promoting effects, especially in relation to chronic disease prevention and amelioration, are under development (Gry *et al.*, 2007; Holden *et al.*, 2005; Møller *et al.*, 2007; Rothwell *et al.*, 2012). Integration of assembled bioactivity information with individual genomic and physiologic measurements holds great potential for the development of individually appropriate foods and diets for personalized health improvement interventions.

Health Targets and Model Foods

Functional molecules act on many different physiological systems through a wide variety of biological mechanisms, ranging from substrates for commensal bacterial growth to binding toxins in the blood stream. Defining desirable health traits, and analyzing the biological processes, molecular mechanisms, and molecules necessary for desired health outcomes is an important first step in bioguided processing for bioactive ingredients. As food processors begin the process of

deconstructing the bioactive components of their food waste streams, they may also be guided by knowledge about bioactive composition of similar foods. This section examines the human gut microbiota as an example case for health intervention with bioactive ingredients. It also examines human milk as an example case for modeling known bioactive functionalities of a food and its components. These combined model cases guide the development of scientific and engineering methods mentioned in the case study for bioguided processing in the next section.

Case Study, Health Target: Human Gut Microbiota

Substantial evidence now demonstrates that the intestinal microbiota, the complex mixture of microorganisms that live inside the human intestinal lumen, is an important determinant of health. The intestinal microbiota is essential for the development and function of gut mucosal and systemic immune cells. Imbalances in gut microbiota have been linked to infection, allergic disease, inflammatory bowel disease, and metabolic disease (Abt and Artis, 2009; Albenberg *et al.*, 2012). Intestinal microbiota is also directly linked to immune cell homeostasis (Kalliomaki and Isolauri, 2003). The human microbiota consists of 10–100 trillion microorganisms, representing at least 10-fold more cells than that exist in the entire human body (Proctor, 2011). Metagenomic analysis, the quantitation of all genes from all organisms within an environmental sample, reveals that within the human colon alone, there are 150 times more genes from bacteria than from our own human cells (Qin *et al.*, 2010). These microbes occur in a variety of bacterial population mixtures across individuals, between and within mammalian populations; conferring diverse phenotypic traits in all mammals, including humans. Populations of commensal bacteria are necessary for healthy gut and immune function. Commensal bacteria in the gut can provide a physical barrier that displaces pathogens from receptor binding sites on epithelial surfaces. Commensal microbes also compete for available nutrients with noncommensal microbes. In addition, many commensal bacteria secrete antimicrobial agents that protect the host against pathogens and promote immune system development (Hornef *et al.*, 2002). Establishment of a health-promoting and stable microbiota contributes to both short- and long-term human health. The gastrointestinal microbiota have, therefore, become an important area of study as a health intervention target for functional foods and bioactive molecules.

Recent metagenomic studies have confirmed that bifidobacteria, a genus of bacteria found in human intestinal lumen, are especially enriched in the intestines of healthy breast-fed infants versus formula-fed infants (Yatsunenko *et al.*, 2012). It is now well-established that bifidobacteria can contribute to the prevention and treatment of many animal and human gastrointestinal disorders, such as necrotizing enterocolitis, inflammatory bowel disease, and other colonic transit disorders (Culligan *et al.*, 2009). One specific species, *Bifidobacterium longum*, has been shown to modulate intermediate biomarkers of colon cancer, as well as reduce tumor outcomes (Challa *et al.*, 1997; Reddy and Rivenson, 1993; Rowland *et al.*, 1998; Singh *et al.*, 1997). Because of these conferred health benefits, *Bifidobacterium longum* is considered a probiotic. 'Probiotics' have been defined as "live microorganisms that when administered in adequate amounts confer a health benefit on the host" (Sanders, 2000).

Case Study, Model Food: Human Milk

Whereas probiotics alter the bacterial populations directly, prebiotics help shape the composition of the intestinal microbiota by selectively nourishing commensal bacterial populations. Prebiotics are defined as "selectively fermented ingredients that allow specific changes, both in the composition and/or activity in the gastrointestinal microbiome that confers benefits upon host well-being and health" (Manning and Gibson, 2004). Probiotics and prebiotics are widely used to improve and maintain health (Rastall and Maitin, 2002). Breast milk, the sole source of nourishment for newborns, has been under intense selective pressure over millions of years of evolution to meet the infant's needs to grow and survive (German *et al.*, 2002; Zivkovic *et al.*, 2011). Mother's milk plays a crucial role in directing and educating the infant's immune, metabolic, and microbial systems, enhancing nutrient absorption and delivery, and conferring multiple means of protection between the maternal mammary epithelia and the infant gastrointestinal system. The third most abundant compounds in human milk after lactose and lipids is a class of carbohydrates known as oligosaccharides. Oligosaccharides are chains of monosaccharides between 3 and 20 sugar units in length. Human milk oligosaccharides (HMOs) are indigestible by infants because their secretory enzymes are incapable of cleaving these complex sugars into small enough units to be absorbed through intestinal epithelia. A convincing body of evidence now supports the hypothesis that HMOs are prebiotics that promote the growth of beneficial bacteria, such as bifidobacteria, normally found in the intestine of breast-fed infants (Donovan *et al.*, 2012; LoCascio *et al.*, 2010). HMOs exist as free-floating entities, and may also be conjugated with proteins and lipids. When oligosaccharides are conjugated with proteins, they are sometimes referred to as glycans. In addition to providing selective nourishment to commensal bacteria like *Bifidobacterium longum*, HMOs existing both freely and as glycans attached to proteins and lipids prevent the binding of pathogens to intestinal cells, thereby preventing infections (Coppa *et al.*, 2006; Crane *et al.*, 1994; Morrow *et al.*, 2005; Newburg *et al.*, 2005; Strömqvist *et al.*, 1995).

The molecular deconstruction of mother's milk, and annotation of its effects on infant biology, provides a rich model replete with molecules, as well as molecular and biological mechanisms, through which milk's varied individual and ensemble components confer health (German *et al.*, 2002). Understanding how the components of milk interact for health-improving biological processes is driving the development of new food products. Clinical trials are beginning to show that these products are capable of stimulating and strengthening various health outcomes in infants, immunocompromised elderly, and individuals in the population at large (Sullivan *et al.*, 2010).

Mining Functional Molecules from Food Processing Side-Streams: Promoting Environmental Sustainability While Sourcing Molecules for Health Targets

Environmental sustainability aims to promote long-lasting engineered systems capable of supporting human well-being while having a neutral or positive impact on the surrounding natural environmental systems. Industrial waste streams (often referred to as 'side streams,' 'by-products,' or 'industrial streams') are residual materials resulting from industrial and agricultural operations to create a primary product. Many agricultural and food processing waste streams contain high levels of organic materials that can act as energy sources for aerobic microorganisms. When these streams are released into the environment, microorganisms bloom and create an increased requirement for oxygen in their environment. This phenomenon is referred to as biological oxygen demand or biochemical oxygen demand (BOD). When BOD increases, there is less oxygen in the water for fish and other aquatic organisms to obtain the oxygen they need to live.

The concept of utilizing excess waste from agricultural residues to produce energy or food products is not new. Food makers and engineers have long been exploring suitable technologies to reduce the pollution associated with agricultural wastes by creating novel uses for side stream components. Many processed meat and cheese products are themselves made from byproducts resulting from food processing. More recent is the development of engineering methods to capture bioactive molecules from processing side-streams. Bioguided processing refers to the development of food processing methodologies that preserve the biological functionality of selected components while reducing the environmental impact (often by reducing BOD) of streams (Ward *et al.*, 2004). Bioguided processing capitalizes on recent advancements in high-throughput analytical technologies, combined with novel separation methods, for the characterization and recovery of functional molecules from waste streams.

Table 1 shows some examples of by-products from the food industry including: dairy soybean, wine, coffee, and olive oil side streams. Many functional compounds could potentially be extracted from these side streams. Examples of compounds include oligosaccharides, glycolipids, glycoproteins, and peptides.

Case Study, Sustainable Bioguided Processing I: Scientific Mining of Cheese Whey for Functional Molecules

Many applications await the isolation and characterization of nondigestible oligosaccharides that mimic the protective properties of HMOs. Currently, however, no commercial source of HMO-like compounds (glycans with high levels of sialylation and fucosylation) exist. As a result, the food industry supplements products with simpler inexpensive glycan alternatives. Infant formula manufacturers currently use prebiotic molecules derived enzymatically from the trans-galactosidation of lactose (such as galactooligosaccharides) and fructo-oligosaccharides derived from plant inulin (Jenkins *et al.*, 1999). Although these oligosaccharides mimic the prebiotic effects of human milk to a certain degree, they are structurally and compositionally different from HMOs and lack some HMO biological functions.

Table 1 Example of five commodities and the side streams they generate

Main product	*Side streams*
Cheese	Whey
Soybean	Soybean processing waste (fiber-rich spent solids)
Wine	Wine processing waste (wine-grape residues and pomace)
Coffee	Residues from coffee processing (spent grounds)
Olive oil	Olive oil wastewaters

Whey is the liquid part of milk that separates from the solid curds during cheese-making and was traditionally considered a waste product; it, therefore, serves as an excellent example of a biological waste stream that was only recently shown to contain functional molecules. Cheese whey has been viewed as a secondary product from cheese production for centuries. Recently, cheese whey from cow's milk, also known as bovine whey, was shown to contain complex milk oligosaccharides (Barile *et al.*, 2009). These bovine milk oligosaccharides (BMOs), decorated with fucose and sialic acid, respectively, are structurally and compositionally analogous to HMOs, and confer many of the same health outcomes (Aldredge *et al.*, 2013). Bovine whey also contains bioactive glycolipids, glycoproteins, and peptides similar to those found in human milk (Smithers, 2008). In addition to being inexpensive and available in large quantities, whey is an attractive model source of bioactive molecules because removal of these molecules greatly reduces the pollution index of whey, making cheese processing more sustainable. Because bovine whey is considered 'generally regarded as safe (GRAS),' it presents a unique source for food-grade BMOs and other bioactive molecules. Owing to the wide variety of cheeses and dairy side-streams available, researchers must characterize and quantify the varied processing streams relative to bioactive components, and thus commercial and bioguided remediation potential.

Although varying according to cheese processing methods, approximately 9 l of whey are produced from 10 l of bovine milk during cheese making. More than 400 000 metric tons per year are being generated worldwide by dairy processors. Global demand for cheese is fueling massive growth in cheese production, with more whey generated every year (U.S. Export 5 Year Trend, 2013). The type of cheese manufactured and the processing technologies employed for cheese production determine the type and composition of the resulting bovine whey. Within the cheese manufacturing process, perhaps the most profound determinant of whey composition is the method used for casein precipitation. Typically, whey consists primarily of water (93% of the volume), lactose, proteins, minerals, and vitamins (Walzem *et al.*, 2002). Whey contains almost 50% of all solids present in whole milk (Marwaha and Kennedy, 1988). Only 50% of whey is currently further processed into various food and feed products (Baldasso *et al.*, 2011). Dairy processors are facing the problem of surplus whey disposal and reutilization, posing serious economic and environmental problems. High BOD of whey poses major problems for waste water treatment, and a substantial cost for treatment plants (Marwaha and Kennedy, 1988). Similarly,

whey waste negatively alters the physical and chemical structure of soil, and a prolonged exposure can cause a decreased crop yield, limiting possibilities for irrigation with whey. Untreated whole liquid whey is used as an animal feed, particularly for pigs, although transport of liquid whey over any distance is both difficult and expensive (Schingoethe, 1976). The amount of whey that can be incorporated into animal diets is trivial compared to the volumes that need to be absorbed (Schingoethe, 1976). Therefore, greater utilization of whey components is desirable to avoid these economic and environmental costs. Recent advances in technology now allow the separation of protein and lactose (Scott and Krishnapillai, 2012).

Ultrafiltration is a type of filtration that uses hydrostatic pressure to force liquid through a filter fine enough to retain colloidal particles and high molecular weight molecules. Though ultrafiltration systems have been in commercial use for approximately 30 years, dairy processors have been slow to adopt these systems for whey processing because of a high price of implementation and difficulties with large-scale membrane processing, including membrane fouling (Cuartas-Uribe *et al.*, 2009). The major technological breakthrough in the commercial production of whey proteins was the development of scalable ultrafiltration systems that yielded nondenatured whey protein concentrates (WPC). WPC and whey protein isolates (WPI)were developed in the late 1990s and produced mostly by membrane filtration (Morr and Ha, 1993). To obtain WPI, whey is passed through a membrane filter (ultrafiltration) which, because of the structure of its pores, retains the macromolecules while letting the water containing the dissolved smaller molecules pass through. This process allows whey proteins to be separated from lactose, minerals, and other components. Ultrafiltration produces two fractions: retentate (containing all retained molecules) and permeate (containing molecules that permeate through the membrane). The final protein-enriched retentate can be dried to a powder in a spray drying tower. The permeate fraction can likewise be dried to make permeate powder. A profitable process for utilization of whey permeate compounds is still lacking. More research and development is required to maximize whey utilization. Discovery of functional proteins such as lactoferrin in WPC sparked growth in the whey protein market (Smithers, 2008). Although manufacturers are increasingly taking advantage of the bioactive benefits of whey when designing new products, the full health-enhancing potential of whey and whey components is still underdeveloped. Concentration of whey proteins in the retentate leaves behind 'waste' streams in the permeate that often contain functional components like BMO and bioactive peptides.

Component characterization and quantification

The basis of all food formulations is the ability to accurately measure the structures and the absolute amounts of the functional molecules present. Side-streams for bioguided processing requires similar molecular characterization because handling, storage, and production processes may have huge impact on the composition and bioactivity, resulting in an altered material compared to the original substrate. Therefore, the first step in valorization, the process by which value is added to a process or product, is the complete characterization and quantitation of all bioactive components in processing byproducts and side streams. Recently, detailed knowledge of waste composition has grown steadily and is essential to the assessment of all basic applications. Measurement of the overall composition of products, including water content, carbohydrates, proteins, and fats is simple and can be performed by all food industries as part of their routine analysis. Greater analytical expertise and advanced instrumentation and data analysis software are required for the unambiguous characterization of complex chemicals in waste sources. Functional compounds such oligosaccharides, glycolipids, glycoproteins, and peptides, are found in relatively low concentrations, and are extremely heterogeneous and complex in nature. Identification and detailed characterization of these compounds, therefore, demand specific analytical expertise. Even small differences in structure can cause significant differences in function, so structural characterization is essential to accurately distinguish molecular function. To identify their biological functions through *in vitro* and *in vivo* studies, it is necessary to measure those molecules with accurate and sensitive methods.

Many of milk's functional molecules could not be discovered until the right concordance of novel separation and analytical technologies were developed and applied. Many health-promoting components still await discovery due to technical challenges in their identification, isolation, and testing. As analytical technologies advance in sophistication and accuracy, new functional milk molecules are being discovered.

In whole milk, many components mask the analytical signal of others, so some components cannot be detected. Because milk is such a complex mixture, its compartments need to be separated, and then fractioned into molecular classes. Modern analytics allow for the discovery and characterization of hundreds of novel milk compounds with high resolution and high accuracy. Liquid chromatography (LC) paired with electrospray ionization allows the separation of peptides, glycans, and glycolipids for improved mass spectrometric detection. Target proteins and glycoproteins can now be purified from intact milk or other dairy streams by chromatography in order to better characterize these proteins for new bioactivities. The combination of advanced analytics with the new engineering capabilities will allow for high molecular resolution and separation techniques that can be scaled up to semiindustrial and industrial scale for translation of lab-based discoveries.

Many technological breakthroughs have made discovery of new milk molecules possible. These advances include improved separation science, high-resolution detection instrumentation, bioinformatic toolsets (like proteomic software), and genomics (as a tool to guide proteomics). Currently, toolsets exist for the detection of a wide array of free milk oligosaccharides (glycomics), milk lipids (lipidomics), proteins (proteomics), and naturally occurring peptides in milk (peptidomics).

Chemical characteristics: oligosaccharides, glycolipids, glycoproteins, and peptides

Chemical characteristics of oligosaccharides

Milk oligosaccharides can have diverse and complicated structures even though they commonly share a lactose core

consisting of a glucose and a galactose linked via a β 1,4-linkage (Kunz *et al.*, 2000). These oligosaccharides are produced in the mammary gland where several monosaccharides are added to a lactose core by action of specific enzymes called glycosyltransferases (Urashima and Taufik, 2010). These glycosyltransferases elongate the core by repetitive attachment of galactose (Gal) and *N*-acetylglucosamine (GlcNAc) in β-glycosidic linkage, which are further decorated by multiple resides of sialic acid and fucose (Kunz *et al.*, 2000). Neutral oligosaccharides are composed of glucose and galactose (lactose core) extensively elongated by β1-3 or β1-6 linkages to lactosamine units, and further decorated with fucose residues in terminal positions connected with α1-2,3,4 possible linkages. Acidic oligosaccharides can contain all these monosaccharides in addition to one or more molecules of *N*-acetyl-neuraminic acid (also known as sialic acid) connected with α2-3,6 linkages. The possible arrangement of monosaccharide combinations and linkages results in a structurally complex array of linear and branched oligosaccharide structures. In particular, the structural elements fucose and sialic acid appear to be crucial to the ability of oligosaccharides to act as bioactive components. These five monosaccharides (glucose, galactose, *N*-acetyl-glucosamine, fucose, and sialic acid) are linked in various ways through at least 12 α- and β-glycosidic linkages. The most abundant oligosaccharides in human milk are fucosylated, whereas sialylation is more abundant than fucosylation in bovine milk and cheese whey (Morrow *et al.*, 2005).

Chemical characteristics of glycolipids

Nearly all glycolipids in vertebrates are glycosphingolipids. The glycolipids are composed of two parts: ceramide lipid portion and carbohydrate moiety. The ceramide is formed by attachment of a fatty acid in amide linkage to the long-chain amino alcohol sphingoid base. Ceramide structures vary in length, hydroxylation, and saturation of both the sphingoid base and fatty acid moieties, resulting in lipid structural diversity that imparts the presentation of the attached glycan at membrane surfaces.

In the complex glycolipids, the glucose moiety in head group is typically substituted with β-linked galactose on the C-4 hydroxyl of glucose, to give lactosylceramide. Further the glycans are extended by the addition of different monosaccharides.

Glycolipids are subclassified as neutral (no charged sugars or ionic groups), sialylated (having one or more sialic acid residues), or sulfated according to the carbohydrate moieties. Traditionally, all sialylated glycolipids are known as 'gangliosides.' The most abundant human and bovine neutral glycolipids are lactosylceramide, glucosylceramide, and galactosylceramide (Newburg and Chaturvedi, 1992). GM3(NeuAcα2-3 Galβ1-4Glcβ-Cer) and GD3 (NeuAcα2-8NeuAcα2-3 Galβ1-4Glcβ-Cer) are the major gangliosdes in bovine milk and whey buttermilk (Lee *et al.*, 2011; Rueda, 2007).

Chemical characteristics of glycoproteins

Protein glycosylation, a common posttranslational modification, plays a key role in structural conformation and resultant bioactivity of proteins (Marth and Grewal, 2008; Shental-Bechor and Levy, 2009). This posttranslational modification is involved in various intra- and intercellular processes including adhesion and trafficking (Ohtsubo and Marth, 2006). During biosynthesis, many milk proteins are posttranslationally modified. Milk glycoproteins are present in the whey fraction (lactoferrin), the casein micelle (κ-casein), and also in milk fat globule membrane (lactotransferrin, clusterin, mucin1, and butyrophilin) (Picariello *et al.*, 2008; Charlwood *et al.*, 2002). The common classes of glycans are primarily defined according to the nature of the linkage to the protein. Glycans can be linked to the protein through O-glycosidic or N-glycosidic bonds. N-glycans are the most widespread modification in human and bovine milk proteins.

Chemical characteristics of glycoproteins: N-glycans

N-glycans are attached, via *N*-acetylglucosamines, to the Asparagine residues of proteins in the specific amino acid sequence that is Asn-X-Ser/Thr (where X can be any amino acid except proline). The N-glycan core is composed of 2 *N*-acetylglucosamines (GlcNAc) and 3 mannoses (Man). The N-glycan core is assembled in the endoplasmic reticulum of the cell and then the glycan is elongated by other monosaccharides via the action of enzymes, which determines the degree of branching and the type of linkage (Aebi *et al.*, 2010). Elongation with sialic acid and fucose increases the diversity and complexity of the N-glycan structure (Ohtsubo and Marth, 2006). N-glycans share a common pentasaccharide core region and can be generally divided into three main classes; oligomannose (or high mannose), complex type, and hybrid type. Glycan function varies based on the glycan composition and the site of attachment, and this diversity is involved in the functional activity of a protein.

Chemical characteristics of glycoproteins: O-glycans

O-glycans are frequently linked to the polypeptide via *N*-acetlygalactosamine (GalNAc) to a hydroxyl group of a serine or threonine residue and can be extended into a variety of different structural core classes. Casein glycomacropeptide or GMP is the prototype O-glycan found in cheese whey: it is a casein-derived peptide that is also present in human milk and may contain up to five different types of O-linked oligosaccharides chains (usually sialylated glycans) (Minkiewicz *et al.*, 1996).

Chemical characteristics of peptides

Peptides are chains of amino acids resulting from the cleavage of larger proteins. In milk, these peptides contain all 20 amino acids. Whether these peptides have complex three-dimensional structures remains unknown. The average length of naturally occurring peptides in whey is 13.3 amino acid residues long with a range between 7 and 25. The average peptide mass is 1502.728 Da (range 687.346–2925.334) (Dallas *et al.*, 2013a,b).

Basic lab-scale separation methods

Basic lab-scale separation methods of oligosaccharides

The basic goal of separating oligosaccharides as a biomolecule class from complex matrices including milk has been developed successfully in the microscale as a standard aspect of analysis. Extraction is a crucial step in the characterization and quantification of all milk bioactives by mass spectrometry.

To characterize the oligosaccharides in milk accurately, it is of great importance that the oligosaccharides are isolated from the other milk components such as lipids, proteins, and small peptides. This is currently done by employing physical methods such as a combination of centrifugation and liquid/liquid extraction and solid-phase extraction (Ninonuevo *et al.*, 2006). All these methods are used in sequence to separate the oligosaccharides based on their unique chemical properties, for example, when using reversed phase solid-phase extraction, the hydrophobic lipids and proteins are bound by the C8 silica cartridge, whereas the hydrophilic oligosaccharides are free to pass through the column undisturbed (Barile *et al.*, 2010). A further extraction step involves the purification and concentration of the oligosaccharides by employing graphitized carbon cartridges that allow for the removal of salts, mono- and disaccharides, and remaining proteins while achieving a nearly complete recovery of the oligosaccharides. The specific mechanism of interaction between the complex carbohydrates and graphitized carbon is poorly understood, has not been completely elucidated yet, and assumed to involve both absorption and hydrophobic interaction (Packer *et al.*, 1998). Retained oligosaccharides can be divided into acidic and neutral fractions, hence their properties, and are further analyzed by accurate mass spectrometry. Unfortunately, it is currently impossible to obtain enough quantities of oligosaccharides in laboratory to support prebiotic and other functional studies.

Basic lab-scale separation methods of glycolipids

The analytical methods used for glycolipids require several purification steps. Because of their amphipathic nature, it is currently not possible to purify and measure total glycolipids using a single method. The liquid–liquid solvent system requires a polar and a nonpolar component, and neutral and anionic glycolipids are often fractionated and analyzed separately (Ledeen and Yu, 1982; Merrill *et al.*, 2005).

The general procedure includes separating milk cream by centrifugation. Further separation is then achieved by liquid/liquid extraction based on the relative solubilities in polar and nonpolar solvents. Highly polar glycolipids, such gangliosides, are further enriched on reverse phase solid-phase extraction cartridges. Nonpolar glycolipids are usually fractionated on normal phase chromatography.

Basic lab-scale separation methods of glycoproteins

To isolate glycoproteins, all lipids and caseins have to be removed by centrifugation (to eliminate the cream) and by acid treatment (to precipitate the caseins). Owing to the low concentration of glycoprotein in bovine milk, the resulting whey needs to be significantly concentrated. Glycoproteins can be isolated from other whey proteins by separation methods like ion exchange and affinity chromatography, resulting in very high purity (Barboza *et al.*, 2012; Law and Reiter, 1977). Chromatographic methods allow separation of glycoproteins based on their amino acid sequence or glycan composition (Kletter *et al.*, 2013). For example, lectin immobilized on beads can be used to recover lactoferrin through binding of specific protein-linked glycans (e.g., the lectin called concanavalin A binds α-linked mannose and terminal glucose). These techniques achieve high purity isolation of the protein of interest from complex mixtures like milk and whey. However, for single protein isolation, each step of the chromatographic needs to be optimized for each glycoprotein. The quality of the purified fraction can be monitored by gel electrophoresis and mass spectrometry. The identification of the protein can be validated by Western blot and peptide mass fingerprinting. Novel protocols are being developed to achieve site-specific analysis of milk glycoproteins (Nwosu *et al.*, 2012, 2011). These methods involve using aspecific proteases to digest the proteins into short glycopeptide chains whose structural elucidation is accomplished by using accurate mass and tandem mass spectrometry.

Basic lab-scale separation methods of glycoproteins, N-glycan purification

To identify the glycans, they can be released by a chemical method or the use of a commercial enzyme, peptide-*N*-glycosidase F (PNGase F), which cleaves between the Asparagine residue and the first *N*-acetylglucosamine of the N-glycan core. One of the advantages of the enzymatic method is the release of a large variety of glycans, except those containing a fucose α (1–3) linked to the terminal *N*-acetylglucosamine residue of the N-glycan core. PNGase F is not able to cleave the linkage between the first *N*-acetylglucosamine and the asparagine residue due to steric hindrance. Glycans can be released from the protein in solution or from the Coomassie-stained gel band that contained the glycoprotein (Rendić *et al.*, 2007). Specific exoglycosidases can also be used to get more information about the N-glycan structure. The deglycosylated protein can be eliminated by ethanol purification and the released carbohydrates can be purified by graphitized carbon chromatography and analyzed by sensitive methods like mass spectrometry.

Basic lab-scale separation methods of peptides

Peptidomic analysis of milk's naturally occurring peptides is now possible only through a confluence of novel preparative isolation, analytical separation, analytical detection, and computational techniques. Milk peptides can be isolated by first removing cream by centrifugation, then removing the large proteins via acid precipitation, and finally by removing the salts, lactose, and oligosaccharides by preparative nonpolar (C18) solid-phase extraction (SPE).

Analytical instrumentation and molecular characterization

High-throughput strategies have recently been developed that enable the annotation of the molecular milk components by using advanced analytic tools like mass spectrometry. The advantage of the mass spectrometer is that in many cases it can provide unambiguous identification. Mass spectrometry has emerged as an invaluable technique with a wide array of applications, including food analysis. Its use in waste stream composition analysis is burgeoning. Not only does it yield structural information from the molecule under investigation, but it also provides the molecular weight of the analyte. This is, in most cases, the single most important and discriminating piece of information available because it reduces the number of possible identities of the analyte. Another advantage of mass spectrometry is its sensitivity. Chemical species identification can be obtained from subfemtomole amounts of analyte. Mass spectrometry can also provide quantitative information if appropriate standards are used.

Liquid chromatography separations – A closer look

The combination of chromatographic techniques, such as the high pressure liquid chromatography (HPLC) microchip, with mass spectrometry reduces the time of analysis and generates more detailed information by separating molecules before they reach the detector. Employing LC in conjunction with mass spectrometry can identify molecules with identical composition but different structures, and therefore, different biological activities. A recent review published in the *Journal of Chromatography A* detailed the astonishing increase in the number of papers, more than 300 per year, that utilize HPLC–mass spectrometry for food analysis (Di Stefano *et al.*, 2012). A 50-fold increase since 1991 makes HPLC–mass spectrometry the fastest growing analytical technique for food analysis (Di Stefano *et al.*, 2012).

Commercially available HPLC chip devices with integrated enrichment and separation columns packed with graphitized carbon allow isomer-level separation of glycans. (Ninonuevo *et al.*, 2006, p. 200; Niñonuevo and Lebrilla, 2009) When these microchips are coupled with high performance mass spectrometry, such as the high accuracy time-of-flight (TOF) mass analyzer, all isomers can be rapidly analyzed in a precise and reproducible manner (Niñonuevo *et al.*, 2005, 2007; Tao *et al.*, 2009; Wu *et al.*, 2010a,b).

Mass spectrometry – A closer look

Mass spectrometric platforms are capable of detecting more compounds in a single run than other traditional analytical tools. With small molecules, this high precision measurement can lead to a single compositional possibility. A variety of mass spectrometers can be employed for detection of functional milk components (e.g., TOF, Fourier transform ion cyclotron resonance (FTICR)). These mass analyzers have high resolution and are highly sensitive. Mass spectrometers possess several components: (1) a sample inlet that introduces samples into the mass spectrometer, (2) an ion source that generates gas phase ions from analytes, (3) a mass analyzer that separates ions based on their mass-to-charge ratio (m/z), (4) a detector that monitors the ion current and converts it into a signal, (5) a computer and data system that coordinates the functions of the instrument components and records and stores the data, and (6) a vacuum system that removes molecules, thereby providing a collision-free path for the ions from the ion source to the detector. In tandem mass spectrometry, neutral gas molecules are added to the ion path, causing collisions that result in molecular fragmentation.

Ionization techniques

A variety of ionization techniques are used for mass spectrometry. Two soft ionization methods – matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ESI) – have led to an enormous increase in the utility of mass spectrometry for biological macromolecules such as proteins and glycans.

Mass analyzers

High mass accuracy and resolution mass analyzers, such as TOF and Fourier transform ion cyclotron resonance (FTICR) analyzers are often used for mass profiling. Ions of interest can be isolated and fragmented for identification. LC-MS/MS analysis with a triple quadrupole mass spectrometer in multiple reaction monitoring (MRM) mode provides excellent quantitation (when used with internal standards) due to its high accuracy. MRM provides a highly selective and sensitive determination of a compound of interest in a mixture.

Molecular characterizations of oligosaccharides

Identifying and quantifying milk oligosaccharide structures has been a major challenge. Functional studies previously involved either a limited number of structures or little to no structural information. Recently, methods for the comprehensive analysis of milk glycans has evolved, involving advanced separations methods and high performance mass spectrometry (Leoz *et al.*, 2013; Strum *et al.*, 2012; Wu *et al.*, 2012). The developments of new analytical techniques have significantly improved our knowledge about the structures of milk oligosaccharides (Pfenninger *et al.*, 2002). Bovine milk is potentially an excellent source of commercially viable HMO mimetics. Until recently, the analysis of oligosaccharides from bovine milk was hindered by the lack of effective analytical tools. Recently, the lower abundant oligosaccharides from bovine milk were characterized and shown to contain complex structures similar to HMO (Barile *et al.*, 2010; Hua *et al.*, 2012; Wickramasinghe *et al.*, 2011). There are 40 unique BMO in bovine colostrum, including 24 acidic structures containing sialic acid, and 16 neutral oligosaccharide structures containing glucose, galactose, and *N*-acetylglucosamine (Tao *et al.*, 2009). The identified oligosaccharides in bovine colostrum include several structures identical to neutral and acidic HMO, including LNnT (lacto-*N*-neo-tetraose), LNnH (lacto-*N*-neo-hexaose), 3′-SL (3′sialylactose), and 6′-SL (6′sialylactose). Recently, the bovine glycome was established for several dairy breeds (Barile *et al.*, 2009; Sundekilde *et al.*, 2012; Tao *et al.*, 2008). Recent analysis of bovine dairy streams by accurate mass spectrometry has revealed the presence of previously unknown complex fucosylated and sialylated oligosaccharides, analogous in composition and structure to the ones found only in human milk (Aldredge *et al.*, 2013). This discovery has led to the hypothesis that these specific oligosaccharides can be isolated from dairy streams, individually characterized for structure, and reconstituted into a pool of protective oligosaccharides that mimic the activities observed for human milk.

Advances in mass spectrometry have enabled identification and determination of milk oligosaccharides at the molecular level as well as provided detailed information about their specific utilization by intestinal bacteria; sequencing of the whole genome allowed a new level of understanding of the specific prebiotic activity (LoCascio *et al.*, 2010; Sela *et al.*, 2012; Wu *et al.*, 2010a,b). Analysis of oligosaccharides from bovine milk has been hindered by the lack of effective analytical tools to analyze complex carbohydrate structures present in low concentrations. The development of analytical tools such as microchip LC combined with high-performance mass spectrometry allowed significant progress in the examination of oligosaccharides in bovine milk and milk from other mammals (Tao *et al.*, 2011, 2010, 2009, 2008).

Molecular characterizations of glycolipids

The first survey profiling for glycolipids is often exploratory, thus called an 'untargeted' approach. Milk glycolipids have been identified using MALDI mass spectrometry (Bode *et al.*, 2004; Lee *et al.*, 2011). High resolution mass analyzers, such as FTICR, provide rapid identification of these molecules. A number of differences between bovine milk and human milk have been observed. Major bovine and human milk gangliosides are GD3 and GM3; whereas, the ion intensities of ganglioside species are different. Identification of gangliosides relies on tandem MS to confirm the compositional and structural assignments.

Upfront chromatographic separation of a glycolipid and phospholipid mixture makes it possible to detect more ions by minimizing ion suppression and ultimately increases sensitivity (He *et al.*, 2007; Lee *et al.*, 2012). LC-tandem mass spectrometry (MS/MS) analysis in multiple reaction monitoring (MRM) mode has become an effective technique for highly specific and accurate quantitation of glycolipids, especially when present in low abundance (Lee *et al.*, 2013; Sorensen, 2006; Zhang *et al.*, 2012). This technique could be used to quantitate the exact amounts of glycolipids in dairy products and side streams (Lee *et al.*, 2013).

Unlike free milk oligosaccharides, glycoconjugates are more complicated due to the respective protein or lipid moieties. Glycolipids are heterogeneous in their properties due to variation in the fatty acid or sphingosine structure of the ceramide lipid component as well as the diversity of the oligosaccharide. For example, glycolipids composed of ceramides with short fatty-acid side chains and large oligosaccharide chains will be much more soluble in polar solvents than glycolipids composed of ceramides with long fatty-acid side chains and short oligosaccharide chains. Therefore, the classical analytical methods use multiple chromatographic analyses along with extensive sample preparation. Moreover, the analytical methods fail to describe in precise details both the lipid and glycan moieties simultaneously. The method often requires huge amount of samples, which impedes the functional studies for those low abundant molecules.

Molecular characterizations of glycoproteins

Glycosylation of proteins is a complex posttranslational modification with high diversity of possible structures. Some biomolecules, including protein and nucleic acid, can be easily sequenced but the elongated branches and diversity of N-glycan isomers complicates their unambiguous characterization. Enumeration of each fully described glycoprotein chemical species remains a significant scientific challenge. Isomer separation and identification are important steps for glycan characterization. Identifying site occupancy on the protein, of each varied glycoform is also necessary for complete glycoprotein characterization. Furthermore, the concentration of ruminant glycoproteins is low in milk. Bovine milk lactoferrin concentration is ten times lower than human milk. Glycoprotein characterization requires the use of highly sensitive and specific instruments. Rapid profiling of glycans can be obtained by MALDI-TOF-MS (Hansen *et al.*, 2010). MALDI-TOF has been successfully used in a large number of studies to characterize N-linked glycans (Finke *et al.*, 1999; Niñonuevo and Lebrilla, 2009). Biological samples like milk and serum typically contain a mixture of neutral and sialylated glycans. Neutral glycans are typically analyzed in presence of sodium, as $[M+Na]^+$ in the positive mode and sialylated glycans are typically analyzed as $[M\text{-}H]^-$ in the negative mode (Harvey, 2006). Biological samples typically contain a mixture of neutral and sialylated glycans. Accurate analysis of sialylated glycans is difficult because the sialic acids can be lost during the ionization process (Hansen *et al.*, 2010; Harvey, 2006). MALDI-TOF-MS provides the accurate mass and the relative abundance of glycans in the sample. Studies on the milk N-glycome reveal 51 different compositions for bovine milk and 38 for human milk with notable abundance differences of fucosylated and sialylated glycans between the 2 species (Nwosu *et al.*, 2012).

Molecular characterizations of peptides

Peptides can be ionized without in-source fragmentation by MALDI and ESI. These soft ionization techniques were required for the analysis of proteins and protein components. Mass analyzers that can be used for peptide analysis include TOF, Orbitrap, triple quad, and FTICR. LC is typically applied for peptide detection. Increased LC separation simplifies detection by decreasing ion supression and providing isobar separation for clear tandem fragmentation.

Once isolated, peptides can be separated with a C18 analytical column and detected by a mass analyzer. Even low ppm precision intact mass measurement is not enough to identify the exact peptide sequence. Therefore, compounds can be sequentially isolated and fragmented. The fragment spectra can be analyzed for components of the peptide to provide evidence for which possible sequence is correct. As the mass spectrometer typically produces thousands of tandem spectra in an hour run, data must be processed via automated software. Data can be exported and the fragment spectra analyzed with proteomic software such as X!Tandem. A search for a aspecific enzymatic cleavage patterns must be performed. To narrow the possible peptide sequences, a milk protein-specific library can be employed as the basis for the search rather than the usual complete human proteome. Peptides identified from automated analyses can be compiled as libraries of known peptides with mass, retention time, and a unique identity. These libraries can then be applied back to the mass spectrometer runs of the sample for peak volume extraction. Peak volumes can be compared between identical peptides across different sample sets.

Data analysis software

Mass spectrometry data includes mass and peak intensities. Mass combined with retention time from LC separation can be used to identify molecules. Tandem mass spectra can provide further evidence for identification. Compound structure can be elucidated from empirical formula calculations and the vast amounts of accurate mass data generated by these precision instruments. Data analysis software simplifies aggregation of large amounts of data and eases its interpretation. Using data analysis software (e.g., Agilent MassHunter Qualitative Analysis software), discrete molecular entities defined by the combination of retention time and mass are generated. Highly accurate measured masses of the different molecular species combined with their isotopic patterns and collisionally

induced dissociation (CID) fragments are additionally used for empirical formula calculation and structure elucidation. Relative quantities of each molecule can be also derived.

Analytical instrumentation and molecular characterization: Molecular libraries and structural information resources for molecular identification

Construction and application of mass and retention time-based molecular libraries allows streamlined, high-throughput identification of molecules. Once molecules are identified, they can be compiled into libraries. With software, these libraries can be used to search the chromatograms for previously identified molecules based on accurate mass and retention time. Application of a molecular library within spectral analysis software (such as Agilent MassHunter) allows fast matching of ions with the library and computational extraction of each compound's abundance. These libraries typically include the mass, retention time, and identity of the compound. More sophisticated libraries such as Agilent Personal Compound Database Library also employ representative MS/MS spectra for each compound to increase the certainty of the match. For these libraries, the MS/MS spectra of the unidentified compound must match, within a margin of error, the peaks in the reference spectra. These libraries allow high-speed molecular evaluation of samples from milk and dairy streams.

Mass and retention time-based libraries have been created for more than 80 HMOs (Wu *et al.*, 2010a,b). Aldredge has recently assembled a BMOs library (Aldredge *et al.*, 2013). More than 50 oligosaccharides have been identified including several novel fucosylated oligosaccharides. The construction and use of these libraries enable automated identification of these oligosaccharides. Application of the BMO library facilitates identification of oligosaccharides in commercial dairy streams.

Current structural libraries for glycolipids are limited in size. Partial tandem mass spectra libraries for glycolipids are available from LipidMaps (Dennis *et al.*, 2005; Fahy *et al.*, 2007). Dallas recently published a library of endogenous human milk peptides (Dallas *et al.*, 2013a,b). Hua and Kronewitter have established, for mice and humans, respectively, libraries of N-linked glycans (Hua *et al.*, 2013; Kronewitter *et al.*, 2009). These libraries of structural identification are based on accurate mass, reproducible retention time, and effective isomer separation. This approach obviates the need for continued *de novo* structural elucidation by providing researchers with look-up identification mechanisms. These spectral libraries additionally provide a resource against which bioactive molecules isolated from clinical trial specimens (e.g., feces, urine, and serum) can be matched, thereby advancing the field of molecular diagnostics.

Scaling Up: PILOT and Industrial Scale Extraction of Functional Compounds from Food Matrices and Processing Effluents

Chemical and biosynthesis methods for production of functional compounds are often cost prohibitive. Yet pilot-scale production methods are necessary to produce functional molecules in sufficient quantities for evaluation in functional assays, as well as tolerance and efficacy clinical trials. Lack of affordable, commercially feasible, large-scale methods for bioactive molecule production has hindered progress in knowledge that could be gained from *in vivo* and *in vitro* functional tests. Food matrices and food processing effluent streams are a rich source of bioactive compounds with potential for highly efficient industrial-scale extraction and production (Agyei and Danquah, 2011). Many food sources, such as milk, eggs, soybeans, fish, corn, wheat, and many others, contain naturally occurring functional compounds – or can release functional compounds when subjected to specific processing conditions such as enzymatic hydrolysis and microbial fermentation (Korhonen *et al.*, 1998; Korhonen and Pihlanto, 2006). While seeking out molecules for their biofunctional properties like antithrombotic, antihypertensive, immunomodulatory, antioxidant, antimicrobial, to name a few, bioactive molecule extraction from food matrices also requires extensive knowledge of intrinsic molecular physical–functional properties like solubility, foaming, and gelling, among others (Agyei and Danquah, 2011; De Moura *et al.*, 2011a; Hernández-Ledesma *et al.*, 2011; Kinsella, 1979). Consideration of bioactive molecule physical–functional properties determines, in large part, the best methods and technologies to use for their extraction and production.

Effects of Processing Conditions on Extraction, Recovery, and Functionality of Extracted Compounds

Maximizing extraction efficiency of target compounds while preserving their bioactivty is essential to improving the economic viability of any bioactive compound extraction procedure. High yields may result in poor bioactive functionality under suboptimal conditions. Alternate methods of extraction yield products with varied chemical structures and biological functionalities. The form in which the target compound is released from its matrix is also a factor in final recovery yield and functionality (De Moura *et al.*, 2011a,b; Clydesdale, 2005).

Because composition, structure, and functionality of food compounds can be significantly affected by processing conditions (Jung *et al.*, 2012; Kinsella, 1979; Korhonen *et al.*, 1998; De Moura *et al.*, 2011a), the methods used to produce, extract, and recover functional molecules from food must be carefully considered. Processing conditions such as heating, shear, pH, enzyme treatment, and solvent-ratio can exert major effects on physical–chemical and bioactive properties of food compounds. Although the impact of food processing conditions on proteins and peptides from various sources have been extensively reported in the literature (De Moura *et al.*, 2011a,c; Korhonen *et al.*, 1998), less information is available regarding other classes of bioactive compounds such as oligosaccharides, glycolipids, and glycoproteins. These functional molecules have only recently begun to be fully characterized. Determining the impacts of processing conditions on the structure and function of bioactive compounds is essential. Consideration of postextraction storage conditions on bioactive molecule stability is similarly important, and is an emerging area of investigation.

Challenges for Stream Fractionation and Enrichment of Functional Molecules

The quest for alternative sources – The human milk oligosaccharides example

The limited supply of HMOs precludes their use as an industrial source for large-scale production of prebiotics. Researchers are currently investigating alternative sources of complex oligosaccharides in sufficient quantity for *in vitro* and clinical studies. Various chemical and biological synthesis strategies have attempted to produce glycans with bioactivities mimicking those of HMOs. Currently, much simpler structures, including inulin, fructo-oligosaccharides, and galacto-oligosaccharides are commercially available and have been tested in clinical trials. These simple structures are either extracted from plants or obtained by β-galactosidase-catalysed conversion of lactose. These glycans stimulate the growth of intestinal bacteria, but they do not selectively stimulate the growth of commensal bacteria to the exclusion of undesired bacteria (Ninonuevo and Bode, 2008). These oligosaccharides are nonselective because their simple structures mean that only a limited number of bacterial glycosidases are required for their degradation. Solid-phase oligosaccharide synthesis is useful to synthesize small amounts of simple oligosaccharides for use as standards in analyses (Tolborg *et al.*, 2002), but production of large quantities needed for human trials is currently economically prohibitive.

Commercial-scale sources of complex oligosaccharides that more closely mimic the structures and functions of HMOs are needed for clinical trials to determine their bioactivities, efficacy, and tolerability in humans. As structures of oligosaccharides from a variety of potential sources are identified and quantitated, new sources and methods for their recovery will emerge.

Current status of dairy industrial processing techniques for functional molecules

In addition to the scientific challenges around identification and quantitation, commercial extraction of functional molecules from milk has largely been limited by lack of economically feasible large-scale isolation technologies and methods. Yet industrial adoption of larger-scale methods for isolation of functional bovine milk components could lead to improved infant formulas or other therapeutic applications. Current processes to fractionate and purify functional molecules (including oligosaccharides, glycolipids, glycoproteins, and peptides) from dairy sources at laboratory-scale include cream separation, reverse phase, ion-exchange, and affinity chromatography, gel and capillary electrophoresis, selective precipitation, and membrane filtration. Low productivity, large effluent production, product degradation, and operational complexity have stalled commercial adoption of many laboratory fractionation/enrichment methods.

Membrane filtration is used most frequently by industry for the fractionation and enrichment of proteins-, peptides-, and oligosaccharides fractions (De Moura *et al.*, 2011b; Korhonen and Pihlanto, 2003; Martinez-Ferez *et al.*, 2006; Zydney, 1998). Membrane technology has also been widely used for isolation and fractionation of whey proteins in the dairy industry since the early 1970s (Cheryan, 1998; Pouliot, 2008). Stepwise filtrations using different pore size membranes have been used to separate numerous milk components according to their size (Ramchandran and Vasiljevic, 2013). Membrane-based separations can be effectively and economically implemented at large scale, which is necessary for most industrial applications (Zydney, 1998). Membrane microfiltration is often used in dairy applications to remove milk fat (Maubois, 2011). Microfiltration is also used to filter bacteria enabling the production of milks with extended shelf life (Elwell and Barbano, 2006). Ultrafiltration has been used to recover and fractionate whey proteins and casein micelles from milk, and the combination of ultra- and nanofiltration has been used to recover oligosaccharides (Cheryan, 1998; Goulas *et al.*, 2003; Zydney, 1998). Application of membrane separation technology in the dairy industry improves existing processing lines. The possibility of recovering previously lost compounds with specific and known bioactivity enables development of new products while reducing pollution, thereby enhancing process efficiency, profitability, and environmental stewardship (Rosenberg, 1995).

Purification of extracted functional molecules is an essential component of downstream processing. The high cost of some solid-phase extraction techniques has hindered the scale-up of LC for large-scale molecular purification. Ongoing innovations are helping to make these techniques economically feasible in the near future (Scoma *et al.*, 2012). Attempts to improve the feasibility of large-scale chromatography through regeneration and reuse of both solid-phase materials and solvents are ongoing and will be critical to enable future scale-up of this technique (Scoma *et al.*, 2012). Scientific advances that promote the creation and production of safe and easy to handle columns, optimized for high throughput yet capable of utilizing different resins, all at a broad range of scale, will surely propel the bioprocessing fields and industries forward.

Case Study, Sustainable Bioguided Processing II: Pilot-Scale Extraction of Functional Molecules from Cheese Whey

Once known as a major pollutant of waterways, bovine cheese whey is now recognized as a pool of valuable bioactive compounds. Increasingly, knowledge of whey bioactive compounds is transforming whey from a pollutant and source of inexpensive animal feed to a source of functional compounds that can increase the health and personalization values of foods and ingredients.

Although WPC and WPI are the two major industrial processing recoveries of whey (Ramchandran and Vasiljevic, 2013), it is now known that use of high temperatures within these traditional whey processing methods has been linked to reduced product functionality, opening up the opportunities to use membrane technology as a more forgiving processing method (Marcelo and Rizvi, 2008). Whey processing filtration techniques currently includes microfiltration for fat and microorganism removal as a pretreatment of whey for the manufacture of WPC and WPI; ultrafiltration to recover and fractionate whey proteins; and nanofiltration and reverse osmosis to concentrate and demineralize whey and whey permeates (Ramchandran and Vasiljevic, 2013).

The production of WPC by membrane filtration leaves behind a permeate that contains oligosaccharides and naturally occurring peptides. Currently, this fraction is mainly utilized as a source of lactose or disposed by the manufacturer, so this current waste stream holds great potential for dairy industry recovery of functional molecules. A general schematic for possible future industrial-scale applications for isolation and fractionation of functional milk molecules such as oligosaccharides, glycoproteins, and glycolipids and from bovine milk is presented in **Figure 2**. After pasteurization, residual lipids are separated from whey by centrifugation in a cream separator (Cheryan, 1998) (1). Once the lipids are removed, skim whey is further subdivided (2) by a 10 kDa membrane to capture whey proteins. After the proteins are removed, lactose is hydrolyzed (3) into glucose and galactose to prevent capture of lactose in the nanofiltration membrane. Nanofiltration (4) of the lactose-hydrolyzed whey permeate yields a solution with oligosaccharides, peptides, and some mineral salts in the retentate while glucose, galactose, and most mineral salts pass through the membrane into the permeate. This clean permeate solution can be used as fermentation and growth media. Lipids can potentially be further fractionated from cream to obtain a selective enrichment in glycolipids. Solvent extraction (5) can be used to fractionate acidic glycolipids from neutral lipids (Svennerholm and Fredman, 1980). Further purification of glycolipids can be achieved with reverse-phase chromatography. Reverse phase chromatography can also be employed at large-scale to remove other components from the glycolipids and generate enough purified glycolipids for *in vitro* studies. Whey proteins are not all glycosylated so additional steps of fractionation are necessary if increased purity is desired. Proteins can be precipitated (6) by adding ethanol; ion exchange chromatography and lectin-affinity chromatography can be used to recover glycosylated proteins (Saito *et al.*, 1991). Oligosaccharides in the nanofiltration retentate are further purified (7) from

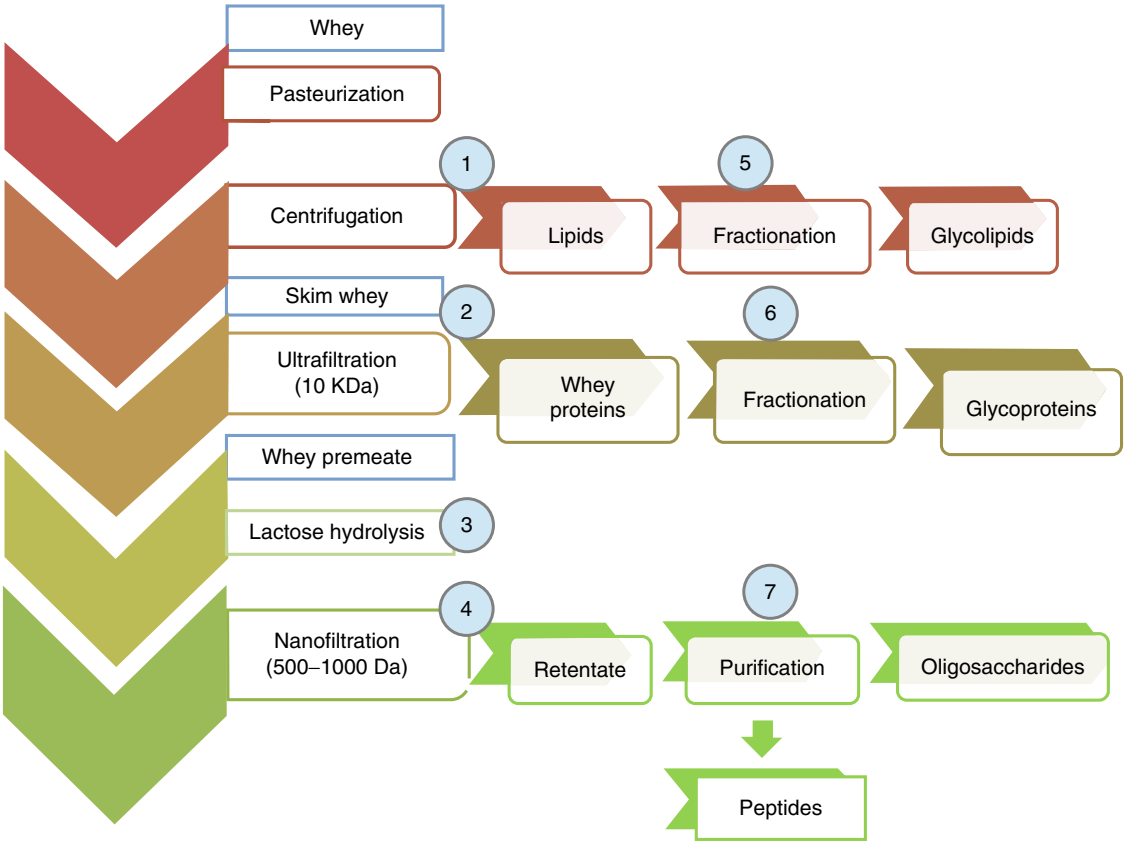

Figure 2 Processing the workflow for whey bioactive component extraction. (1) After pasteurization, residual lipids are separated from whey by centrifugation in a cream separator. (2) Once the lipids are removed, skim whey is further subdivided by a 10 kDa membrane to capture whey proteins. (3) After the proteins are removed, lactose is hydrolyzed into glucose and galactose to prevent capture of lactose in the nanofiltration membrane. (4) Nanofiltration of the lactose-hydrolyzed whey permeate yields a solution with oligosaccharides, peptides, and some mineral salts in the retentate while glucose, galactose, and most mineral salts pass through the membrane into the permeate. This clean permeate solution can be used as fermentation and growth media. Lipids can potentially be further fractionated from cream to obtain a selective enrichment in glycolipids. (5) Solvent extraction can be used to fractionate acidic glycolipids from neutral lipids. Further purification of glycolipids can be achieved with reverse-phase chromatography. Reverse-phase chromatography can also be employed at large-scale to remove other components from the glycolipids and generate enough purified glycolipids for *in vitro* studies. Whey proteins are not all glycosylated so additional steps of fractionation are necessary if increased purity is desired. (6) Proteins can be precipitated by adding ethanol; ion exchange chromatography, and lectin-affinity chromatography can be used to recover glycosylated proteins. (7) Oligosaccharides in the nanofiltration retentate are further purified from monovalent salts and monosaccharides resulting from lactose hydrolysis by applying continuous or batch diafiltration.

monovalent salts and monosaccharides resulting from lactose hydrolysis by applying continuous or batch diafiltration (Goulas *et al.*, 2002).

Improvements in separation technology

Although ultrafiltration has been extensively used to concentrate proteins, its use as a fractionation technique for proteins of similar size has been hindered by low selective separation.

Diafiltration, the addition of water to wash microsolutes from the retentate, increases the purity of macromolecules retained in the retentate. Development of multistage, continuous operations using robust membrane systems, alternate membrane configurations, and diafiltration have contributed to the recent success of this technology in the dairy industry (Cheryan, 1998). Glycoproteins from whey protein concentrate can be isolated from the whey or casein protein fractions at industrial scale by traditional chromatography techniques. The application of positively charged membranes to separate proteins from cheese whey improved fractionation selectivity by more than 600% when compared with uncharged membranes (Bhushan and Etzel, 2009). Charged membranes show promise in fractionating proteins with similar size but different isoelectric points at specific pH and ionic strength (Arunkumar and Etzel, 2013; Bhushan and Etzel, 2009). This exciting area of research holds promise for advancements in membrane life-time, efficacy of ligands based on processing time, and resistance to cleaning procedures. All of these processing variables will help determine economic feasibility for future industrial adoption.

When higher levels of purification are required, industrial-scale application of ion-exchange chromatography could be the best choice, for example, for lactoferrin isolation (Law and Reiter, 1977).

The major challenge of oligosaccharides purification from cheese whey is enriching the oligosaccharide fraction while reducing the content of lactose and other simple sugars that lack selective prebiotic activity. Lactose removal is important for oligosaccharide bioactivity studies because, due to its predominance in whey, it can confound functional studies on the biological activity of oligosaccharides. Among the small-scale processes to produce oligosaccharide-rich fractions reported in the literature, an inexpensive and scalable approach to recover biologically active oligosaccharides from milk was developed (Sarney *et al.*, 2000). Sarney and colleagues have investigated the use of combined lactose enzymatic hydrolysis with a two-step filtration (ultra- and nanofiltration), followed by diafiltration in order to remove the monosaccharides and residual lactose. This approach enabled a significant enrichment of the retentate in oligosaccharides: more than 50% of goat milk's free oligosaccharides were recovered.

Examining the Health Benefits of Cheese Whey Components

Whey contains several classes of bioactive molecules. In addition to previously mentioned oligosaccharides, whey contains bioactive glycolipids, glycoproteins, and peptides. Glycolipids are lipid molecules that are decorated with sugar residues. Similarly, glycoproteins differ from regular proteins because of the oligosaccharide residues that form a coat around specific regions of the protein. This glycan coat differentiates glycolipids and glycoproteins from their nonglycosylated molecular brethren in terms of their bioactivity, as well as the methods scientists must use to detect, isolate, characterize, and quantify these molecules. Free floating peptides found in whey also exhibit important health conferring bioactive properties, and require special isolation and quantitation methods to accurately associate their unique structures with bioactivities.

Health benefits of oligosaccharides

In addition to guiding the development of the human intestinal microbiota, by promoting growth of commensal organisms and protecting infants from a variety of pathogenic and inflammatory conditions, HMOs provide myriad functions including modulating the immune system, enhancing cognitive development, and providing protection from toxins and pathogenic diseases (Kunz *et al.*, 2000; Newburg, 2001; Newburg *et al.*, 2004; Reinhardt *et al.*, 2009).

The ability of HMOs to support the competitive overgrowth of protective *Bifidobacterium infantis* within the intestine is at the core of its value to infants. Bifidobacterial colonization of the gut protects the infant by lowering the pH and reducing accessibility via spatial inhibition (Urashima and Taufik, 2010). Furthermore, bifidobacteria are protective because they are involved in fighting infections caused by bacterial pathogens (Sakata *et al.*, 2005; Thibault *et al.*, 2004). Consequently, a bifidobacteria-dominated microflora may decrease the risk of gastrointestinal diseases. Additionally, evidence suggests that the presence of beneficial intestinal microbiota during the first few weeks of life is important for the development of the immune system (Eiwegger *et al.*, 2004; Martino *et al.*, 2008; Sudo *et al.*, 1997). The proposed mechanism for this immune support is that specific bacteria interact with immune cells in the intestines, increasing cytokine and antibody production (reviewed by Seifert and Watzl, 2007). Lower levels of *Bifidobacterium* species during the neonatal period are associated with increased risk for allergic diseases (Björkstén *et al.*, 2001; Kalliomäki *et al.*, 2001; Sepp *et al.*, 1997). From a genomic prospective, bifidobacteria represent a remarkable example of coevolution because they contain a cassette of genes encoding glycosidases capable of metabolizing HMOs (Sela and Mills, 2010). Mammalian evolution likely selected for this specific group of bacteria based on the genes required to degrade complex oligosaccharides.

Approximately 200 oligosaccharides have been identified, of which nearly 100 are now fully characterized structurally (Tao *et al.*, 2011, 2010; Wu *et al.*, 2010a,b). Linking the precise complex structural characterization of each of these carbohydrates with their multitude of biological functions is an area of ongoing investigation.

In addition to stimulating beneficial microflora, HMOs also inhibit pathogenic bacteria in the gut. Recent research suggests that breastfed infants of mothers who produce specific HMO are protected against diarrhea (Morrow *et al.*, 2004). HMO containing fucose and sialic acid share common structural motifs with glycans on the infant's intestinal epithelia known to be receptors for pathogens. Such structures imply that their presence in milk provides a defensive strategy by acting as decoys to prevent binding of pathogens to

epithelial cells, thereby protecting infants from disease (Newburg *et al.*, 2005). Oligosaccharides containing α1,2-linked fucose (Newburg, 2009; Newburg *et al.*, 2005) or terminal NeuAcα2,3 Gal residues (Bouchara *et al.*, 1997; Stins *et al.*, 1994) block specific pathogens from binding to the intestinal epithelium.

The ability to metabolize HMO is not exclusively restricted to bifidobacteria. *Bacteroides fragilis* and *Bacteroides vulgatus* also exhibit *in vitro* growth on HMO (Marcobal *et al.*, 2011). Interestingly, the ratio of Bacteroidetes to Firmicutes has been associated with the prevention of obesity (Jumpertz *et al.*, 2011; Turnbaugh *et al.*, 2009). Firmicutes dominate over Bacteroidetes and Actinobacteria in the gut of obese children and adults (Armougom *et al.*, 2009); and the proportions of Firmicutes and Bacteroidetes are significantly greater in obese compared with normal weight adults (Abdallah Ismail *et al.*, 2011). Children maintaining a normal weight have greater populations of bacteria from the phylum Actinobacteria, especially bifidobacteria, in infancy compared with children becoming overweight (Kalliomäki *et al.*, 2008). An increasing number of studies report strong correlations between altered microbial composition and development of metabolic diseases and obesity (LoCascio *et al.*, 2010; Serban, 2011). These investigations suggest that anomalous development of the microbiota early in life may be associated with metabolic dysregulation later on; therefore, manipulation of the gut microbiome by prebiotic supplementation in childhood may be an effective way to improve human health. Using prebiotics to modulate the microbiota is a novel research direction for treatment of obesity.

Because oligosaccharides were discovered in whey permeate only recently, most of the *in vitro* research on oligosaccharides to date has been performed with small amounts of oligosaccharides isolated from human milk at the lab scale (LoCascio *et al.*, 2010; Ward *et al.*, 2006). Investigating the catabolism and fermentation of HMO by bifidobacteria has revealed that some strains of bifidobacteria have unique capabilities, and thus preference for consumption of specific oligosaccharides (LoCascio *et al.*, 2010). Additionally, the presence of sialic acid and fucose in terminal positions act as a shield, thus rendering HMOs inaccessible to intestinal bacteria that do not possess the necessary enzymes (glycosyl hydrolases) (Marcobal *et al.*, 2010).

Genomic analysis of *Bifidobacterium infantis* and *Bifidobacterium bifidum* – two related strains that grow well on HMO – revealed distinctive gene clusters that are specifically induced during growth on HMO (Sela *et al.*, 2011; Sela and Mills, 2010). *In vitro* studies with cell-lines demonstrated that HMOs enhance bifidobacteria persistence in the gut by improving the integrity of intestinal barrier function via regulation of tight junction proteins (Chichlowski *et al.*, 2012).

Recent research also demonstrates that in a mouse model, sugar-specific consumption by bifidobacteria, as well as bacterial production of acetic acid, improves intestinal barrier function (Fukuda *et al.*, 2011).

Antiadhesive activity of free HMO has been described for *Vibrio cholera* (Coppa *et al.*, 2006), *Salmonella fyris* (Coppa *et al.*, 2006), enteropathogenic (Coppa *et al.*, 2006) and enterotoxigenic (Morrow *et al.*, 2005), *Escherichia coli*, *Streptococcus pneumonia* (Andersson *et al.*, 1986), and caliciviruses (Morrow *et al.*, 2005). Because HMOs are excreted in urine of breast-fed infants, it is likely that small amounts of oligosaccharides are absorbed intact from the gastrointestinal tract and end up in the systemic circulation (Obermeier *et al.*, 1999; Rudloff *et al.*, 1996); thus pathogen inhibition by oligosaccharides may occur at parts of the body other than the intestines. Similar to HMOs, BMOs have been shown *in vitro* to block adhesion to target cells, of seven enterotoxigenic *E. coli* strains isolated from diarrheal calves (Shabana *et al.*, 2013; Shabana *et al.*, 2013) and *Neisseria meningitides* (which causes meningitis and septicemia) (Hakkarainen *et al.*, 2005). Furthermore, 3′-Sialyllactose (NeuAc(α2–3)Gal(β1–4)Glc) – a major constituent of both BMO and HMO – inhibits the binding of *Helicobacter pylori* to human duodenal cancer cells (Simon *et al.*, 1997, p. 199).

Milk oligosaccharides have also been shown to have antiviral actions. Some HMO bind to the dendritic cell-specific ICAM3-grabbing integrin (DC-SIGN) and block adhesion of HIV-1 by its gp120 protein (Hong *et al.*, 2009). Binding of gp120 to DC-SIGN is essential for the virus to enter the dendritic cell, from where it is passed to T cells (Hong *et al.*, 2009). The oligosaccharide blocking of DC-SIGN binding sites may be partially responsible for the low risk of HIV-1 transmission through breastfeeding (Hong *et al.*, 2009).

Clinical studies on the oligosaccharides' potential to modulate the gut flora, to affect different gastrointestinal activities and to influence inflammatory processes are still lacking, as the large amounts of milk oligosaccharides needed are not available yet. Implementation of these activities resulted in the first human trial conducted using purified BMO extracted from cheese whey (ClinicalTrials.gov Protocol Record 264294). The bifidogenic effect of human milk has been recently shown both by characterization of oligosaccharides in breast-fed infant feces and by the study of intestinal microflora. Several studies demonstrate that oligosaccharides withstand the pH of the stomach and resist enzymatic digestion in the gastrointestinal tract (Boehm and Stahl, 2007; Gopal and Gill, 2000). Some HMOs are absorbed and then excreted into the urine intact, implying that inhibition of intestinal and urinary pathogens by HMOs is quite likely in breast-fed infants (Chaturvedi *et al.*, 2001). Breast-fed infants compared to formula-fed infants are at a lower risk of gastrointestinal disease, respiratory disease, and other infectious diseases, and have chances of a better development of their gastrointestinal tracts and immune systems (Lawrence and Pane, 2007; Newburg, 2005; Pabst *et al.*, 1997). The studies purport that milk bioactive molecules are likely to be beneficial for human health not only in a short-term manner, but throughout life.

Health benefits of glycolipids

Glycolipids are ubiquitous components of animal cells and are abundant in the apical membrane of the epithelial cells of the intestinal tracts (Simons and van Meer, 1988). The acquisition of glycolipids through the diet may be an important contributor to health because of their interactions with bacteria. Glycolipids are found in milk fat and can also be extracted from whey cream and whey buttermilk (Lee *et al.*, 2013). Moreover, glycolipids may have an important role in the promotion of intestinal immunity development (Rueda, 2007).

Glycolipids are thought to play an important role in cell self-recognition (Yamakawa and Nagai, 1978). They are also the site at which many pathogens bind and attack human cells (Fantini *et al.*, 2000; Otnaess *et al.*, 1983). When milk fat globules are secreted, they are completely coated with the cellular bilayer membranes of the epithelial cells of the mammary gland. As a result, milk and particularly the milk fat membrane is considered to be rich in glycolipids. However, the specific benefits of glycolipids are unclear, and their role in milk continues to be a subject of research.

Ingestion of milk glycolipids may contribute to the prevention of infection and immunity (Rueda, 2007). Glycolipids act as pathogen decoys, which compete for pathogen binding sites and block pathogens from binding to their host cell receptors in the mucosa (Idota and Kawakami, 1995). The binding of the different bacterial pathogens to their ganglioside receptors is structure-specific. Human milk gangliosides inhibit the growth of *E. coli* and *V. cholera* enterotoxins (Otnaess *et al.*, 1983). Milk gangliosides are also known to inhibit the adhesion of *E. coli* to human intestinal carcinoma cells. Another notable aspect is the ability of gangliosides to modulate the development or behavior of cells of the immune system. Recent research also reported a specific effect of GM3 and GD3 on dendritic cell maturation suggesting a role for these milk glycolipids (especially ganglioside GD3) in modulating the process of oral tolerance during the first stages of life (Brønnum *et al.*, 2005).

Along with milk oligosaccharides and glycoproteins, glycolipids act as prebiotics. Ganglioside-supplemented infant formula has been reported to modify the intestinal ecology of preterm newborns, increasing the bifidobacteria content and lowering that of *E. coli* (Rueda *et al.*, 1998). In addition, the influence of dietary gangliosides on several parameters related to the development of the intestinal immune system, such as cytokine and intestinal IgA production, has also been described in animal models (Vazquez *et al.*, 2001). Animal studies demonstrate that inflamed intestinal mucosa has fewer gangliosides than healthy intestinal mucosa (Park *et al.*, 2007). Accelerated catabolism of gangliosides in the intestine increases proinflammatory signaling, inflammatory markers, and susceptibility to pathogens. Dietary gangliosides are able to replace the mucosal gangliosides that are progressively degraded in inflammatory conditions (Miklavcic *et al.*, 2012). Restoring proper ganglioside abundance and function in the intestine could resolve inflammation, increase resistance to infection, and improve gut integrity to induce remission of conditions like necrotizing enterocolitis, inflammatory bowel diseases, and Crohn's disease (Miklavcic *et al.*, 2012). Most of the clinical studies used glycolipids from whole animal organs (i.e., brain); however, the biological issues associated with extracts of brain tissue from any source preclude its use in routine food applications without exhaustive safety testing. Bovine colostrum contains high levels of gangliosides and is, therefore, an ideal source to extract pure gangliosides that are analogous in structure to the gangliosides present in the intestinal mucosa (Lee *et al.*, 2013).

Health benefits of glycoproteins

The most abundant whey proteins are β-lactoglobulin and α-lactalbumin, representing approximately 70% of the total protein content of whey. However, whey also contains low abundance glycosylated proteins like lactoferrin and lactoperoxidase that display interesting bioactive properties. Several authors have demonstrated an array of glycoproteins bioactivities including antioxidant, antibacterial and antiviral action, as well as immunomodulation, which contribute to the increased populations of commensal organisms in intestinal microbiota (Legrand *et al.*, 2005; Lonnerdal and Iyer, 1995; Orsi, 2004; Seganti *et al.*, 2004). Lactoferrin appears to protect the intestinal cells against viral or bacterial gastroenteritis. Lactoferrin can target immune cells, including lymphocytes and macrophages and has the apparent ability to modify their function (Ward *et al.*, 2002). This glycoprotein may also be implicated in the inhibition of proinflammatory biomolecules such as cytokines (Sanchez *et al.*, 1992).

The ability of glycoproteins to behave as simple prebiotics is well-documented; however, precise determination of functional components (protein and the glycan) relative to enrichment of specific bacterial populations remains a topic of inquiry. Glycan structure determination offers another dimension for characterizing the relationship between structure and function of the protein. Characterizing and quantifying the relative contributions of varied functions of glycosylation on individual milk and whey proteins remains a significant challenge.

For example, bovine lactoferrin, a multifunctional glycoprotein in milk, contains four N-glycosylation sites, whereas human lactoferrin contains only two sites. *In vitro* studies show that lactoferrin absorbs iron, inhibits bacterial growth, and enhances the growth of commensal bacteria (Sanchez *et al.*, 1992). As glycosylation of human lactoferrin varies significantly within human lactation (Marcobal *et al.*, 2011), association of glycosylated molecular species with consumption of specific bacteria remains unknown.

The first step of microbial infection *in vivo* is the interaction of glycan from the epithelial surface of the host with bacterial adhesin that will bind the glycoproteins present at the cell surface. Recent studies support the hypothesis that glycans linked to milk protein may help protect against microbial attacks (Farnaud and Evans, 2003). Emerging evidence shows that protein-linked glycans protect intestinal mucosa by inhibiting the attachment pathogens, thereby protecting infants from gastrointestinal infection. By inhibiting bacterial growth and attachment to the epithelial cells, lactoferrin has been shown to exhibit antimicrobial activity against, *E. coli*, *Listeria monocytogenes*, *S. pneumonia* (Murdock and Matthews, 2002; Yekta *et al.*, 2010). Lactoferrin's antimicrobial activity has been shown to be related to the amino acid chain (Farnaud and Evans, 2003), but a role for the carbohydrate chain can be speculated. Lactoferrin can also exhibit a protection against bacteria due to its iron binding capability. The protein limits bacterial growth by making iron unavailable. Other mechanisms are involved in the antimicrobial activity of lactoferrin, including binding to bacterial and mammalian cell receptors to block the adhesion of pathogens (Valenti and Antonini, 2005). However, not all mechanisms have been well elucidated, including the role of the glycan part in protein function.

Recent *in vitro* studies indeed revealed that the glycan part of human lactoferrin decreases *Salmonella* infections of

cultured human intestinal epithelial cells (Caco-2 cells) (Barboza *et al.*, 2012). *Salmonella* is one of the most common pathogens infecting humans. It appears that specific monosaccharides such as fucose may play a specific role in inhibition of epithelial adhesion of this pathogen. Senkovich proposed the structure of a human lactoferrin complex with pneumococcal surface protein A, as one possible microbial defense mechanism (Senkovich *et al.*, 2007). Mucin 1 and 4 (known milk proteins) inhibit the binding of enteric bacteria to intestinal epithelial cells FHs 74 Int (derived from normal human fetal intestine) and Caco-2 (derived from human colon adenocarcinoma; Liu *et al.*, 2012). Whey glycoproteins may therefore represent a therapeutic source against infant infection caused by *Salmonella* as well as other pathogens.

Infant supplementation with bovine lactoferrin revealed a decrease of digestive tract infection and chronic infection caused by *Giarda* species in infants (Ochoa *et al.*, 2008, King *et al.*, 2007).

Health benefits of peptides

A large number of milk peptides produced by *in vitro* proteolysis have been found to be functional beyond their simple nutrient provision as amino acids (Dallas *et al.*, 2012). Activities of milk peptides include immunomodulation (Jørgensen *et al.*, 2010; Migliore-Samour *et al.*, 1989), opioid-like activity (Brantl, 1984; Kampa *et al.*, 1996), antimicrobial action (Aniansson *et al.*, 1990; Liepke *et al.*, 2001; Strömqvist *et al.*, 1995), and probiotic action (Azuma *et al.*, 1984, p. 198; Bezkorovainy *et al.*, 1979; Liepke *et al.*, 2002). These peptide fragments are not functional when constrained in the context of intact milk proteins (Schanbacher *et al.*, 1997). Site-specific proteolysis releases these enjoined fragments. The best described example is the *in vitro* digestion of human lactoferrin protein: the gastric digestion of this molecule operated by the enzyme pepsin peptide fragment lactoferricin that has potent and specific bactericidal properties (Bellamy *et al.*, 1992). Most of these peptides are not naturally occurring – they were produced by *in vitro* digestion, some with the goal of recreating peptides that would be produced in digestion.

There is currently no clinical research on naturally occurring peptides from human or bovine milk. However, peptides produced by *in vitro* digestions of several milk proteins (mostly the caseins) have been analyzed in a few *in vivo* models. The ensemble of naturally occurring peptides in human milk inhibits growth of *E. coli* and *Staphylococcus aureus* in plate-based radial diffusion assays (Dallas *et al.*, 2013a,b). This article represents the only study of the *in vitro* actions of naturally occurring milk peptides. A large body of work, however, exists on the *in vitro* actions of *in vitro* digested products from purified milk proteins (largely the caseins). These studies have shown a variety of *in vitro* actions including antimicrobial (Liepke *et al.*, 2002, 2001), immunomodulatory (Jørgensen *et al.*, 2010; Migliore-Samour *et al.*, 1989), and opioid agonist/antagonist actions (Brantl, 1984; Kampa *et al.*, 1996). For example, *in vitro* digests of purified human milk lactoferrin promote the growth of bifidobacteria (Liepke *et al.*, 2002). This function further supports the glycan-based prebiotic effects of milk. However, it is not known whether the effectiveness and selectivity is enhanced when these peptides are glycosylated. Bovine lactoferrin hydrolysates produced by pepsin digestion were shown to protect against foodborne pathogens, such as *Salmonella*, *E. coli*, *L. monocytogenes*, and *St. aureus*, in an *in vitro* assay (Murdock and Matthews, 2002). Both human and bovine lactoferricin have been shown to have activity against the human papillomavirus, a known risk factor for cervical cancer (Mistry *et al.*, 2007). These peptides may affect the gut, intestinal epithelium, and the immune system, but the required *in vivo* studies have not yet been carried out.

Effective separation from bovine milk processing streams of the aforementioned biomolecules, combined with evidence of their health benefits, is leading to new classes of bioactive food ingredients. Current research suggests that concentrating certain bioactives from whey permeate can be a cost-effective process for the valorization of whey permeate into high quality, profitable novel dairy ingredients. Given the massive quantities of bovine dairy streams available for capture worldwide, large-scale production is possible with current technologies. Although bioactives in whey are less abundant than in breast milk, existing manufacturing capabilities based on membrane filtration and chromatography will make it possible to isolate these components in enough quantities to carry on the needed studies for clinical validation. These lines of research set the stage to enhance and improve existing prebiotics by translating the evolutionarily linked beneficial association between human milk and their associated beneficial bifidobacteria.

Conclusion and Future Directions

For many years bovine milk was considered a nonviable source for human milk-like glycans because they were thought to be simpler than human milk. The study of glycosylation on protein and lipids was hindered by inherent complexity and low abundance. Low abundant bioactive molecule discovery and recovery is now made possible by modern chemical analytical techniques like mass spectrometry. These high-tech methods provide windows through which compounds can be discovered, characterized, and quantified. Bovine whey provides a model for the ways in which many food processing streams can be interrogated and mined. With massive amounts of agricultural byproducts available worldwide, the process of identification, extraction, and delivery of health-promoting bioactive molecules from these streams hold great promise for the future of food process engineering. Assembly of the molecular fingerprints bioactive compounds into food- and organism-specific spectral libraries is hastening the process by which new compounds can be identified. As libraries are built, bioactive molecules are identified and isolated, and their efficacy and tolerance proved out through clinical and laboratory testing, the process of building knowledge bases about bioactive molecule sources and appropriate uses are further enabled.

Databases of bioactivity are being developed, but standardized infrastructures for annotation, integration, query, and reporting on aggregate knowledge about bioactive chemicals, their food sources, physical properties, bioactive mechanisms, and efficacy/tolerance in individuals

remain to be built. Building semantically integrated on- and off ramps for access to data within each knowledge domain along the food-to-health information superhighway has the potential to collapse the bioactive ingredient development life cycle, propelling related fields forward. Collapsing the food ingredient product development life-cycle effectuates quicker delivery of innovative food products for personalized health improvement. Utilizing such information stores in bioguided analysis and design of agriculture and food processing side streams can transform waste into value-added products, reduce disposal costs, lower the environmental impact of these waste streams, and improve the health of the population.

Domestication of Animals

TR Famula, University of California, Davis, CA

© 2014 Elsevier Inc. All rights reserved.

Introduction: What is Domestication?

The subjugation of fire, the invention of the plow, and the domestication of animals would seem to be the springboard for the rapid explosion of civilization that started nearly 10 000 years ago. However of the three, only the last one involves a collaborator. In the development of tools, like the fire and the plow, our species can claim almost all the credit; but the domestication of animals? That takes a willing collaborator. The process, some might say the 'invention,' of domestication would fail to succeed unless there was benefit to both the people involved and the animals asked to join our community. A topic of endless fascination and speculation, the domestication of animals will always be of interest. It is a process and force for the coevolution of species, a force that continues to shape life on this planet.

However as the plow is considered as an important invention (Pryor, 1985), an obvious question arises. If we wish to till the earth, where does the strength come to do so? And that is where the need to consider the entry of domesticated animals; a source of power and strength, a component of work. As will be seen, though there are a myriad of uses for animals today, such as food, clothing, entertainment, research, and companionship, ancient societies did not domesticate animals for what might be thought to have been their most obvious purpose – food. It is doubtful that our ancestors began this process by thinking: "perhaps we can make yogurt," and then domesticated cattle, horses, and sheep to meet that desire. Instead domestication seems to have moved from initial desires for power and entertainment, perhaps even an element of "can I do this," to all the impacts we see today (Bulliet, 2005). Indeed, as seen during the investigation of the first domesticated animal, the dog, there may have been no goal at all, just a gradual process that was not deliberate or of any conceived direction (Clutton-Brock, 1995).

Herein is outlined this fascinating journey, covering the 'when' of domestication, the 'where,' the 'how many times' and when possible the 'how' it was done, or the 'why' was this undertaken. Then considered are the impact of this important invention, the impact on the animals, and of course the impact on us. Ideally, in this article, there will be a meaningful blend of general principles and specific examples.

Where to begin? Perhaps, it is best to start this journey with a definition to provide a concrete identity of the topic that is explored. The most comprehensive definition is that of Price (Price, 1999): A domestic animal is one that is bred in captivity for purposes of economic profit to a human community that maintains mastery of breeding, territory, and food supply. A fundamental component of this concept is one of genetic change. Domesticated animals are different from their wild ancestors. The human control of breeding has made it so. At the heart of this distinction is the human construct of breed. Therein lies the key distinction between domesticated animals and tamed or captive ones. Animals we domesticate are the ones we control, and in that control we choose parents and mates with a direction in mind. Over the course of time, that continued pressure of selection gradually but measurably changes the animal and its genome. This is the essence of animal breeding, and it is a key distinction in the creation of domesticated animals.

Though this definition is comprehensive in its description of the animal, a final element that may be missing is the recognition that this process involves mutual change. One is reminded almost every day that the animals have changed, just look at the distance between wolves and dogs. However, what is often overlooked is how we are different from our agricultural ancestors. Domestication changed us, and continues to change us. Seeing this as a process of coevolution is critical to our understanding. The *Homo sapiens* of 12 000 years ago are not the *Homo sapiens* of today. Moreover, a sliver of that difference can be traced to our evolving relationship with the animals we brought along with us on this journey. The aspects as to how and why this happened is considered now.

Species of Domesticated Animals

Though clearly an important and fascinating question, no one who has ever thought about the 'when and where' of domestication should expect a definitive concrete answer. How could there be? This process was not only undocumented by our ancestors but it is also not a yes/no process. Domestication, and the acceptance of animals as partners in our lives and survival, has been a gradual process. A little more each day, a little closer each year, a bit more dependent as a society advances. It is not unlike asking 'when and where did modern humans begin.'

Nevertheless, there are some tell-tale signals of where and when this process began. For the evidence, both genetic and archeological data point to the same general time regardless of location; the end of the last ice age, some 12 000 years ago. Throughout this article, the unit of time has been kept consistent, regardless of the measure used in any original article cited. That unit, BP, for Before the Present, is typically a measure based on radiocarbon dating, using AD 1950 as the base year of calculation. In source articles, readers may find the notation of BC, for Before Christ, or the now preferred BCE, for Before the Common Era. There are yet other authors who define events with terms such as the 'fourth millennium BC.' Using the author's notation above, the author using this phrase would be referring to a time period from 4000–3000 years BC, or from 5950–4950 years BP.

The accumulation of evidence from three broad geographic regions is considered: the Near East, the Far East, and Mesoamerica, extending as far south as present day Peru. This oversimplified description includes the domestication of cereal grains in the Near East dating to 9000 years BP, the domestication of maize in the Tehuachan Valley of present day Mexico

 doi:10.1016/B978-0-444-52512-3.00230-8

more than 5000 years BP, and rice cultivation in the Far East some 7000 years BP (Bar-Yosef, 2012; Harris, 2012).

Realizing this represents a considerable swath of time, it is nevertheless interesting to address the comparative simultaneity of agricultural development across the ancient world. Why did agriculture begin at this time? Did the idea travel? Did people in one area suggest this process to their neighbors and 'bring' domestication with them? Or did indigenous people arrive at this invention on their own? Anthropologists now seem to prefer the last alternative (Bellwood and Oxenham, 2008; Cauvin and Watkins, 1994) that as the climate change of the ending Pleistocene era advanced, the rapidly changing biology surrounding human communities almost 'pointed' to humans exploiting this bounty. Still, the transition from nomadism and the hunter/gatherer to sedentism and farming was hardly revolutionary (Lewin, 1988). The process was slow, with fits and starts, failures and limited success along the way. Nevertheless, eventually a transition was made, a transition from which turning back to the past life of hunting and gathering was not possible. Moreover, once that line had been irrevocably crossed, the long process of identifying, subduing, taming, and eventually domesticating animals began.

The list of domesticated animals is remarkably short. Although the list of candidates would appear impossibly long, the table of species that made the transition from wild to human dominated is limited. Among the large herbivorous mammals one would list sheep, goats, cattle, horses, pigs, camels, llamas, donkeys, water buffalo, and yaks. Other large herbivores that are considered domesticated are mithans, bali cattle, and reindeer. Among the birds that have been domesticated, the authors list chickens, ducks, geese, and turkeys. A handful of other animals that are considered domesticated would be dogs and cats, rabbits, mice and rats, and other rodents useful in laboratory work, and a small assortment of aquatic species useful as a food resource like trout, salmon, and catfish. In constructing this list, it is worth considering the earlier definition, along with an assessment of genetic change. In the end, domestication is about human needs and human goals. That is why, ultimately, the line between tame/captive and domesticated, though gray and blurry in some places, rests on the notion of 'breed.' Domesticated animals are constructed around the notion of breed, a population of animals with distinguishable, heritable characteristics.

Why then, is this list so short? Why are so few species called into service by human societies? This topic has been addressed by many authors (Budiansky, 1999; Diamond, 1997) and many competing ideas have been put forward as potential explanations (Anderson, 1998; Darwin, 1900; Sauer, 1969; Trut *et al.*, 2009). Nevertheless, a consensus is building around the exploitation of neoteny as the 'fuel' that drives the domestication process (Trut *et al.*, 2009). Neoteny is the expression of juvenile traits in adults of any species, essentially the juvenilization of the individual. In the context of animal domestication, the critical component of the process would be the exploitation of variation, especially genetic variation, in neotenic traits (e.g., food begging, reduced fear in confronting foreign species) expressed in older, more adult, individuals. To be able to approach, tame, and control undomesticated animals, these neotenic characteristics of behavior and anatomy would be part of any human's unconscious selection decisions. A series of now classic experiments in the fox demonstrated that selection for juvenile behavior traits produced correlated changes in the physiology and morphology of these now domesticated foxes (Trut *et al.*, 2009). Among the changes observed include floppy ears, curly tails, large eyes, shortened forehead, and a shortened muzzle. This exploitation of the variation in neoteny is now considered to play a similar role in the domestication of the dog (Wayne, 2001) and by extension to the other major species of domesticated animals, including livestock (Clutton-Brock, 1999; Driscoll *et al.*, 2009; Price, 1999).

So to answer, why these animals; apparently these are species that satisfy two essential requirements. They are species that offer some special benefit for human survival, and second, they possess the biological (including genetic) variation in neoteny permitting them to be manipulated and eventually domesticated by our human ancestors. It is thus a two-way street, we have the desire/need and the animal gives rise to the capacity to meet this need.

It is indeed an interesting marriage, one with a unique evolutionary history; a history with three dominant articles. The first article, the longest, is one spanning hundreds of thousands of years under the forces of natural selection imposed by evolution. This is an article where animals and humans led distinct lives, intersecting across the environments they both inhabited and the potential to relate as predator and prey. The second article, no more than several thousand years, spans the transition from wild to domesticated. This article is where the marriage began, and in which it has spent the most time. We are presently in the final, third article spanning little more than a handful of decades. However, it is in this article where we witness the intensive breeding and management practices inherent in modern animal agriculture. It has been in this most recent article that humans have exerted their most powerful pressure and in many ways tying our destiny to theirs. It is now examined what special characteristics are required to make it to this select group of species that has moved from the wild to a state of ownership by a human partner.

Common Principles of Domesticated Animals

A natural question to pose, having grasped the fundamental benefits and challenges of domestication, is to identify what characteristics of a species, beyond exploitable variation in neoteny, can lead to successful domestication. For after all, though there are thousands of potential candidates for domestication, only a relative handful can be included within the confines of the opening definition. "Though many have been called, few have been chosen." There are many candidate species, even to this day. Any list would have to include the American bison, any of the several species of zebra that still roam the African plains, even the elephant, might make lists of suitable candidates. Nevertheless moving these and other species, from candidate to an animal under complete human mastery, remains elusive if not impossible. What is it about the special species where we succeed in imposing our control that makes this process workable?

Diamond, among many others, has listed general criteria that appear to be helpful to the domestication process (Diamond, 1997; Jensen, 2002; Mignon-Grasteau *et al.*, 2005; Price, 1999). Though this list is hardly exhaustive, and exceptions can be identified throughout, this list can be helpful in providing a focal point for discussion. The areas to consider include diet, growth and development rate, captive breeding, disposition, tendency to panic, and social structure. Each of them will be considered individually.

Flexible Diet

The key component of this distinctive principle is competition with humans for food resources. Though there are exceptions (and dogs and cats are perhaps the most obvious), most domesticated animals do not compete directly with human beings for their nutritive needs. Indeed, one of the beneficial attributes of cattle, sheep, and goats is that as ruminants they complement human diets rather than compete (Pond *et al.*, 2005). It is not known whether at the time of domestication, or today, these livestock species are notable for their consumption of byproduct feeds. In the well-established agricultural systems of the developing agriculturalists of the Tigris–Euphrates river basin (Peters *et al.*, 2005), sheep and goats provided a much valued complement to the dry-land grain farming of this society. Put simply: humans ate the seeds, the animals ate the stalks, providing meat, milk, fiber, and manure in the process (Harris, 2012). Together, a viable and sustainable food production system was implemented, and indeed lasts to this day.

Dogs and cats are, of course, an exception, both animals being carnivores and thus more directly competing with their human owners for food resources. Of course, in the case of cats, it is their diet of vermin that makes them so valuable to human agricultural societies (Driscoll *et al.*, 2007). Protection of seed stores from the infestation of mice and rats makes the cat a valuable, if in theory competitive, companion. Dogs on the contrary provide no such simple niche explanation. Instead this closest of human–animal bonds needs more to explain it than simple dietary complementarity.

Contrasting the dog–human relationship with newly domesticated aquatic species like trout, catfish, and salmon are precisely the challenge this topic addresses (Wurts, 2000). The long-term sustainability of salmon culture, a top of the food chain aquatic predator, surely calls into question the wisdom of domestication. Regardless of the species-specific comments, it is clear that as a general principle, the diet of the potential domesticate is clearly among the first questions a would-be domesticator must address.

Growth/Developmental Rate

In today's agricultural economy, a market hog is expected to reach 100 kg of live body weight by 20 weeks of age. A market broiler can make it to 5 lbs by 7 weeks after hatching (Field and Taylor, 2012). Of course, the first domesticated ancestors of these animals did not grow at such accelerated rates. Nevertheless, domesticating elephants, or redwoods, is not a strategy for sustainable success in a society living in 12-month annual cycles. Domesticates must have the capacity for rapid developmental change; the capacity to move from young to economically advantageous in a relatively short time span. The species we raise today, like those cited above, surely satisfy this need. A similar mindset must have been present in our domesticating ancestors. The fruits of their labor, whether to develop a powerful animal 'machine' or to efficiently produce a desired resource, had to be a factor in their 'cost/benefit calculations,' however crude those calculations might have been by our standards today. Though by no means paramount, the notion of near-term return on investment had to have been a component of their 'domestication calculus.'

Human-Directed Breeding

This topic, the human control of breeding decisions of animals raised in human communities, hardly needs emphasis in the discussion for this concept is firmly embedded in the earlier definition of domestication. However, human control over breeding must be paramount in the domestication process. Without the control of which animals are entitled to become parents of the next generation, what is indeed the point of domestication? As one might expect, most species do not willingly forswear this control. The few species that have been domesticated seem to have several common attributes to their reproductive strategies, strategies that are now considered.

The first is promiscuous mating. This refers to the lack of an elaborate (or in some cases even a rudimentary) mating ritual. A more pedestrian means of describing this concept is to say that the animal must 'breed in captivity.' And that is true enough. However, the point to emphasize is one more broadly based. It does a human society no good if animals will 'breed in captivity' but not the precise male and female combinations we desire. That is why the term of promiscuous mating is much preferred, a mating strategy in which females will accept any male that the breeders determine is suitable to meet their objectives. Ultimately, if one is to realize the full potential of animal domestication, human mastery of breeding is essential. This control is among the chief impediments one confronts in taking the first steps to shift a species from its wild state to one of domestication (Zohary *et al.*, 1998).

It may be interesting to speculate overcoming this challenge with the modern tools available for reproductive manipulation. That is, with a more thorough understanding of the physiology of reproduction in a species of interest, it might be feasible to control reproduction in the laboratory, not in the field, pen, or cage. Such options were not available to our ancestors. However, the future of animal domestication may find that the tools of biotechnology can open doors that are closed today. Regardless, the challenge still remains of identifying who gets to be a parent and who does not. That fundamental decision is the key to domestication; our principal power and our principal challenge.

Suitable Disposition

First, do no harm. If taken for granted, the conceit that domestication of wild animals was considered by our ancestors to enhance their survival in a harsh world, then domesticating

animals that would not harm them would seem obvious. Nonetheless, some of the species that are considered hallmarks of the domestication process (e.g., cattle and horses) are capable of considerable harm to their human handlers, including mortally wounding humans who stray just a bit too close to their boundaries. Yet, of course, these animals do have a disposition that can be managed, a disposition flexible enough to be shaped by experience and familiarity with humans (Price, 1984). This is not likely to be said of grizzly bears, the North American bison, or the hippopotamus of Central and Southern Africa. In other words, unpredictable aggressive behavior is likely a character our ancestors considered as they eliminated candidates for domestication. Though perhaps tame as juveniles, needlessly aggressive adults should be easy to eliminate from our list of suitable candidates for domestication. Indeed, it is the plasticity, or lack thereof, of aggressive behavior over the course of an animal's lifetime that is instructive. Juveniles are often easily handled, regardless of their eventual adult disposition. However, fully grown adults, often several times the body weight of their putative human 'masters,' cannot be permitted unexpected violent outbursts. It is that unexpected, unanticipated aggression of a large adult that would seem to be the primary source for their elimination from domestication.

Tendency to Panic

Perhaps not as obvious a characteristic as an aggressive disposition, animals suitable as domesticates must certainly have a demeanor free of panic. Animals prone to flee, and flee quickly, from approaching threats are a safety hazard to themselves and their handlers. Imagine a Grant's gazelle, an ungulate capable of fast acceleration to speeds in excess of 45 mph, forced into an enclosure (Heglund and Taylor, 1988). Sheep and goats deal with threats in a far different manner than these speed-oriented mammals, and their suitability for domestication is evident. This speed, coupled with the associated temperament of nervousness, of the hyperawareness of threats makes such animals unlikely candidates for domestication. Not that attempts have not been made. Rather, one can see and explain the seeds for the universal failure of these attempts.

Social Structure

It is evident in our language; the plural for sheep and cattle are the same as the singular. These successful examples of domestication demonstrate that animals that live in large groups, with a prevailing social structure, have an increased likelihood of being shaped by humans from wild to domesticated animals (Price, 1984, 1999). How conspecifics interact with one another, especially in systems of a dominance/submissive hierarchy can play an important role in the success of domestication. That is because humans can insert themselves in the social hierarchy, a mechanism to force the transition from wild to domesticate.

Like so many other conditions, this 'requirement' of domestication is not apparent in all species that have been successfully domesticated. However it is the dominant paradigm. Cattle, sheep, goats, and horses are all familiar living in large, often gregarious, social structures, where dominance and submission play important roles in the social fabric of the group and individual. However as in any other of the conditions of domestication described in this list, such a 'requirement' can be violated. One need only think of the domesticated cat. These animals are often found as solitary predators, yet have become one of the more ubiquitous of domesticated animals. Thus, the list is more an outline of the general principles than a rigid inventory of hard and fast requirements. However a stable social structure, where individuals know their place and behave accordingly, is a useful tool for humans to have seized on. By manipulating these animals to see us as part of their social environment increases the probability that these animals can be transitioned from wild independent creatures to animals willing to tolerate our control of their food, territory, and breeding.

Domestication is about control; and this crude outline of the principles common to domesticated species (i.e., breeding in captivity, flexibility of diet, avoidance of panic, and a fluid yet stable social structure) provides the 'grease' on the gears of this domestication machine. Though not exhaustive, and certainly not part of a necessary and sufficient test of domestication, these concepts help understand and evaluate what our ancestors had to contend with and the thoughts and plans that must have danced in their heads.

The Where, When, and How of Domestication

Marshaling the Evidence of Animal Domestication

How do we know what we know? Not an unreasonable question. With regard to the process of domestication, what appears simple on the surface becomes more challenging, considering the nature of the information that is sought. As the process of domestication began so long ago, with so little formal documentation, piecing together the evidence of how this important process progressed is as challenging as it is fascinating. So as one take on this important topic, asking why did domestication occur and how might it have progressed, one need also to address questions such as how to measure and detect progress? The detection of evidence for domestication has two major points of attack: archeology and genetics (Bradley, 2006; Zeder, 2006a; Zeder *et al.*, 2006a, b). In either case, whether archeologic or genetic, the goal is to identify the markers of this process. Such markers should be objective measures that can be agreed as stably and consistently evaluated. Of course, as one considers such markers one must assess their suitability to change with the varying stages of the domestication process. Any markers that are considered seriously must be the ones that can distinguish wild animals from domesticates, natural processes from directed, evidence of human intervention in an animal's life cycle. Attempts have been made to study those areas; those elements most likely shaped by human intervention are behavioral changes in the transition from wild to domesticated animals, morphological and/or subsequent genetic changes brought about by this transformation. The combined story, unlocked by both archeologists and geneticists, form the basis of all that is

documented in this article. Each area is considered for its information content in 'decoding' the process of animal domestication.

Archeological evidence for domestication

As the process of domestication is considered, and the path it most likely followed, the components most likely to have been selected first are behavioral (Zeder, 2006a). Any pressure our ancestors brought to bear on changing wild animals into domesticates would have been on behavioral characteristics to exploit. Changing or manipulating the morphology and genes would surely take more time and concentration of effort. However exploiting behavioral variation is a natural beginning, behaviors including social structures and hierarchy, sexual and developmental precocity, tolerance of humans and of potential confinement, and components of panic and reduced aggression to perceived threats (Clutton-Brock, 1999). As domestication proceeded, humans would have, consciously or unconsciously, selected for adaptable elements, adaptable to human interests in reduced aggressiveness, submission to various environmental stimuli, and limitations or to various contributions to sexual and mating behaviors (Hemmer, 1990; Kruska, 1988). However in any of these considerations, documenting these changes is near impossible. Such behavioral adaptations do not leave a hard 'footprint' to be uncovered in the present as the domestication process is being documented. Some evidence does exist to this day, as reviewed in the article of Price (Price, 1984). However unlike other measures of change, behavioral adaptation is a marker that is too variable to assess and too plastic to serve as evidence of domestication's advance. We see it today, but have no way to tell when or where it first distinguished itself from any wild ancestor.

However as domestication proceeded, across time and generations, the morphological and changes induced by human control become measurable. In the case of morphological changes, archeologists have a variety of markers to assess as evidence of the progress of animal domestication. Most prominent among them are the changes in body size, often accompanied by reduced brain/cranial size (Hemmer, 1990; Kruska, 1988). The assessment of collected bones and teeth offer data that can be confidently measured and, usually, reliably dated. An obvious application of using bone samples as markers of domestication could simply be the discovery of the samples outside the natural range of the wild ancestor (Horwitz, 2003; Vigne *et al.*, 2005). Additional observations are also available in the measurement of teeth and bones, such as alterations in composition, microscopic changes in structure, or patterns of wear and disease. Astute observation of putative domestic remains, contrasted with similar measures in verifiable wild remains often serve as evidence for the archeological assessment of the progress in the process of domestication at a given site. One of the more commonly considered, though not always reliable, techniques is the contrast of demographic patterns in remains, usually measured as variation in age and gender composition in populations of wild and domesticated animals. The thought underlying this technique is that the gender/age mix of hunted animals is expected to be different from the distribution in captive versus farmed animals (Vigne, 2008). Though common, this technique is not without its critics (Zeder, 2006c), but nevertheless serves as a helpful measure of the process of domestication, reflecting the gradual transition the animals (and the people) took from wild to herded.

Though likely to have occurred later in the domestication process, archeologists can also make use of the physical remains of settlements that have been built or invented by their human inhabitants. That is, the remnants of animal corrals, pens, and other physical structures intended for animal confinement. Samples of animal manure, feed residues or hoof prints, and the ability to date them, can also serve as reliable signposts of this process (Olsen, 2006), including the discovery of the tools of animal husbandry (e.g., bits for horse bridle, sheep crooks). This assessment also includes detection of food processing equipment (e.g., butter churns) or the residues of animal food products in discovered storage vessels (e.g., yogurt from mare's milk) (Dudd and Evershed, 1998; Outram *et al.*, 2009). Taken across this spectrum, archeologists have been able to generate a rich tapestry of data to support the time, place, and progress of animal domestication.

Genetic evidence for domestication

Complementing, and indeed building on, the extensive body of archeological data is an ever expanding body of genetic data to augment one's understanding of the process of domestication (Dobney and Larson, 2006). As with the archeological data, the first steps along the path of domestication cannot be detected as distinct from the existing natural genetic variation in wild species. However, as the process of domestication advances a recognizable 'footprint' of its impact is left in the genome of our domesticated animals. Moreover, as can be seen, this process also left an impact on our own genome and our evolution as a species. First, the genetic evidence in animals is considered.

As can be seen throughout this article, the bulk of the genetic information assembled is used to shed light on the number and geographic location of domestication events, along with assisting in placing these events in time. Most of the genetic evidence derives from the analysis of neutral (or nearly so) genetic markers and noncoding sections of the genome. Though a few studies (Bradley, 2006; Emshwiller, 2006; Zeder *et al.*, 2006b) have tried to identify the 'genes for domestication,' most of the genetic research conducted to examine the evidence for domestication has concentrated on genetic information as a measure of the process, not of the effect a gene may have on the trait of domestication itself. Although, like any other measure of animal performance, a research aim could be to identify the actual genes that our ancestors exploited to create domesticates. That is, the identification of those genetic variants that create and distinguish the 'new' domesticated species from their wild counterparts.

Most genetic studies of animal domestication make use of mitochondrial DNA (mtDNA). There are obvious advantages in choosing this part of the genome. The most obvious is the relatively rapid rate of mutation of this component in comparison to that of nuclear DNA. Given that domestication began, in geologic terms, a relatively short time ago, this rapidly evolving genetic material provides a powerful resource to evaluate the when and where of animal domestication. For the species we most commonly study (e.g., cattle, goats, and

sheep) the matrilineal inheritance (Griffiths *et al.*, 2004) of mtDNA provides exceptional insight into the domestication process.

There are also investigations that make use of the mammalian male Y-chromosome variation (Götherström *et al.*, 2005; Wheeler *et al.*, 2006), a source of genetic material of patrilineal inheritance that evolves more slowly than mtDNA. One can also find the occasional use of microsatellite DNA from noncoding regions of the genome in some reports (Luikart *et al.*, 2006; Parker *et al.*, 2004). Put simply, all of the genome has found its way into answering questions regarding the domestication process. The preponderance of mtDNA-based reports should not preclude our consideration of other information. However, as stated, this material provides distinctive advantages as attempt is made to assess the time and place of ancient events.

Perhaps the most exciting advance in technology to come forward in the past few years has been the analysis of ancient DNA (aDNA). The vast majority of results discussed in this article are derived from taking tissue samples and extracting DNA from animals alive today, and asking "what processes are likely to have occurred in the past to deliver the genomic variation we see today?" This is a question common to population geneticists regardless of the species, attempting to evaluate the past from the data of the present through our understanding of the forces of mutation, selection, migration, and finite population size. In this way attempt has been made to delve, from sequence variation today, into the forces that have shaped this variation and how such variation contradicts or supports one's views on the domestication process. The advance of technology has also allowed to evaluate the DNA of animals long deceased. Given the ability of the bone to 'preserve' DNA, museum samples of wild animals and their possibly domesticated descendants from generations in the past can now contribute to the genetic analysis of domestication (Fernandez *et al.*, 2005; Leonard *et al.*, 2002; Troy *et al.*, 2001; Vila *et al.*, 2001). This capacity to look back directly provides an extraordinary means of examining the shifting progress of domestication. So though our story on the domestication of animals seems, today, reasonably complete, the likelihood of new ground being broken in the coming years increases every day.

The Major Species of Domesticated Animals

To tell the story of animal domestication, one might hope to organize it as one would a newspaper article. That is, to outline the where, when, and how of the process as distinct, almost independent, subtopics. However on further reflection and investigation, one quickly sees the naiveté of such an approach. The study of this important process is an interrelated story, one that involves all the basic questions simultaneously. Any such article would follow these topics based on a myriad of scientific facts and marshaling of facts. This complexity in documentation of this important story is seen in some of the recent conferences, and the ensuing publications that address this fascinating process. 'Documenting Domestication' (Zeder *et al.*, 2006a) tries to cover this immense area of investigation by considering a two by two table; where plants and animals comprise one main descriptor and archeology and genetics comprise the second. Though it is not possible to cover the comprehensive nature of that volume in this work, attempt is made to consider both the archeological and the genetic data that relate to animal domestication. It is a broad topic, but one that can be distilled into several broad, understandable, and interrelated themes.

For example, consider the potential archeological evidence. Study in this area follows one of the three major trajectories: (1) the study of human settlements and patterns therein, (2) the examination of food residues, especially the analysis of organic residues on cooking and storage artifacts, and (3) the examination of human, animal, and plant remains at these settlements. From this variety of information the simple questions of where, when, and how can be addressed. It is easy to see that the question of where is quite easily addressed, if only by the location of the studied settlement. The question of when can also be discussed, these remains often providing mechanisms of dating that are well understood, verifiable, and repeatable. However archeological discovery has a more challenging objective when asked to address the 'how.'

In a similar fashion, the understanding of genetics can be put to use to also assess the simple questions of where, when, and how. This is especially true with the explosion of molecular genetic information and based on the understanding of the mathematics of molecular evolution. With these tools it is possible to evaluate quite precisely the 'when,' for the processes of evolution and the forces that alter gene frequency are sufficiently understood. These molecular tools also help one understand and unlock elements of the 'how,' for one can trace the footprint of genes across populations to assess migration and breeding patterns that might have occurred generations ago to arrive at the results seen in today's domesticated animals. Though the genes have a hard time telling the 'where,' there is some information that can be extracted on the patterns of animal movement. In short, archeology and genetics combine as powerful tools in the investigation of the domestication process; one clearly informs the other.

How Did Animal Domestication Proceed?

As outlined earlier, and surely is obvious, the people who began the process of domestication did not document their work. Nor could they have, not if expected that documentation to have been covered in the span of several generations. The process of domestication was anything but rapid. This pace reflects both the challenges of the task, and what some might suggest as the reluctance to take on such a project (Diamond, 1997).

To illustrate the potential time span, as well as the detective work used today to uncover the work of the past, the archeological site of Tel Abu Hureya (Budiansky, 1999) is examined. Tel Abu Hureya was a village of continuous human settlement from 11 000 to 7000 years BP in the northern reaches of modern Syria on the banks of the Euphrates River. Archeologists have been able to recover tens of thousands of bone fragments, enough to tell a very interesting, and what is believed to be a typical, story for the advancement of agriculture and the domestication of animals.

At the beginning of this settlement (approximately 11 000 years BP) there is no substantive evidence of an organized food production system (i.e., agriculture). The people of this settlement appear no different from other hunter–gatherer cultures. Even after the domestication of cereal grains, which seems to date to approximately 9500 years BP in this settlement, hunting played a prominent role. The great majority of bone fragments from this time period are of gazelles, with fewer than 10% being the bones of sheep and goats (Saña Segui *et al.*, 1999).

With a more sophisticated analysis, archeologists have provided some fascinating insights into the dietary habits of these people. The sheep and goat bones dated between 11 000 and 8500 years BP show no decisive evidence of belonging to a domesticated animal. However by 8500 years BP an interesting pattern can be uncovered. The milk teeth of young gazelles, an animal that to this day remains hunted and undomesticated, fell into one of the two groups: those with virtually no wear (i.e., newborns) and those with substantial wear (i.e., yearlings) with no teeth discovered between these two mutually exclusive classes (Saña Segui *et al.*, 1999). The conclusion to be drawn: these animals were hunted, killed in the late spring as part of their migration through Tel Abu Hureya. However, the teeth of sheep and goats tell a qualitatively different story.

By 8500 years BP there are sufficient goat and sheep teeth in the sample to quantify patterns of tooth wear. Unlike the two classes of gazelle teeth, sheep and goat teeth show patterns of continuous wear. That is, animals were killed throughout the year, suggesting domestication, and are at the very least, a pattern of close, communal living. The point to sustain is the long time period and gradual transition from hunter to farmer. Indeed, the people of Tel Abu Hureya clearly demonstrate the coexistence of grain farming and animal hunting, coupled with a gradual change to domesticated animals (Bar-Oz *et al.*, 2011; Saña Segui *et al.*, 1999).

This story of the slow adoption of agriculture and the domestication of animals is played out repeatedly, including the advance of this process in Europe and other sites of human expansion (Pinhasi *et al.*, 2005). The driving element of this process appears to be the availability of species with which to work and the pressure of population growth among the societies taking this step (Childe, 1942). Nevertheless, the outline of the domestication story from Tel Abu Hureya leaves us with one abiding conclusion: that domestication is not a moment, but a process, a process that was repeated in many places, at many times, with a variety of species. These facts lead us to ask, what has this process wrought? What have we done to the animals in our care, and indeed to ourselves, as we traveled this path of interdependence?

Impacts of Animal Domestication

Impacts on the Animals

As outlined at the beginning of this article, the purpose of domestication is to demonstrate mastery over an animal's food supply, access to territory, and breeding practices. Within that broad sweep of control, the implication is that this control is done for a reason, with a purpose in mind. In the case of Neolithic people, the mechanism driving any such change might have been poorly understood, but a direction for this change must surely have been present. Today, it is rather thought that the mechanisms of change are understood much better. And indeed we do. However our goals are not fundamentally different from those of our Neolithic ancestors. We wish to shape animals to our own needs, to our own vision of their purpose. And so we have. Though a thorough treatment of all these areas of change is not possible in the space of this article, some of the more important among them are identified. Having set approximately, some 10 000 years ago, to reshape a handful of the world's animal species to our needs and ends, what have we accomplished?

Changes in body size

One of the most common observations of animals, certainly in the initial generations of domestication, is a reduction in body size. The reason for this result may vary from species to species, but the general trend is apparent in the archeological record (Zeder, 2012). One could speculate that a poor, or limited, food supply may lead to reduced growth. However, over the longer term, human handlers may have unconsciously or even consciously selected for smaller, more juvenile easier to manage animals. In the long term, however, this general observation may not fit in all cases. Certainly there are breeds of dog, turkey, or horse that exceed the mature size of their wild ancestor (Field and Taylor, 2012). In these instances, one can surely see the hand of motivated animal breeders, individuals with a clear goal in mind and the steadfast desire to reach that goal.

Modifications of appearance

Absent bones and other physical evidence can span centuries, but are limited in comparisons of appearances between wild and domesticated animals by those occasional cases where the wild ancestor survives. That is, one can see the dramatic changes in coat color and hair quality between dogs and gray wolves. One can directly observe the changes through this direct comparison. Indeed, in the circumstance of comparing dogs and wolves some of the changes have been so great that it is challenging to see the remnants of a wolf in many of the breeds of dog today (Larson *et al.*, 2012). However, the study is no longer limited by direct visual comparison for some of these 'softer' traits. As seen, through the sequencing of ancient DNA, the wild horse coat colors were quite different from the patterns and colors seen today. Animals with little chance of survival in the past can now be protected and encouraged to reproduce.

One can also note the reduction in size (or presence) of horns. In the wild, horns can play a valuable role in defending oneself from predators or in securing food, territory, or mates from conspecifics. As domesticates, horns are a threat to their human handlers and to other animals in the flock or herd. This is another simple example of how domestication modifies the external appearance and functionality of the animals in our care (Zeder, 2012).

One might think of this as the 'price' an animal pays for submitting to the domestication process in the first place. Traditional views of domestication made the process seem to be one of human instigation and human domination.

However the process is now thought to be more of a 'two-way street;' where humans hope to take advantage of this captive resource and the animals 'submit' to the capture, finding this a path to increased access to resources (food, water, and territory) and eventual survival (Budiansky, 1999). Perhaps this exploitation, and selection, for an animal's willingness to live within the confines set by humans is the greatest impact we have had on their morphology, behavior, and appearance (Udell *et al.*, 2010). In our mutual goal, to enhance 'both' our survival strategies, we have shaped each other into a species that was not there at the outset. Neither of us has left the process, which continues still, as we began.

Dramatic physiological changes

No discussion of the impact of domestication on the animals would make sense without a mention of the dramatic changes we have made in the anatomy and physiology of these creatures. No hen, in the wild, would need (or be capable) to lay 250 eggs in a production year; although that is precisely what a commercial laying hen can do in the production and laying facilities we manage today. And what cow would produce more than 11 300 kg of milk in a 10-month lactation? Broiler-type chickens can reach 2.2 kg by 7 weeks of age, and do so on as little as 4 kg of feed. The alteration of the physiology of these animals is staggering (Field and Taylor, 2012); and the changes in many instances have not slowed down.

In virtually every instance of animal domestication, a list of species could be drafted and could distinguish one or more contributions these animals make to human survival and quality of life. Moreover, in nearly every element of such a list one could delineate an exaggerated component of their wild ancestor that humans have exploited to their own needs. Whether it is growth rate, fecundity, fertility, lactation, or components of behavior, the animals in our charge have moved dramatically from the homeostatic midpoint where they were placed by natural selection. Humans have remodeled and overhauled these species, often with discernible negative consequences (Mcgreevy and Nicholas, 1999); and this sweeping set of changes did not occur in a vacuum. Not only have the animals changed, so have we.

Impacts on People

In the end, the whole purpose of this article is to describe the impact of the process of domestication on our view of animals, one another, and how this process has influenced our past as it guides our future. The domestication of plants and animals coincided with and facilitated our transition from small bands of hunters and gatherers into the complex technological society we have become today. As a result, trying to assess the impact of animal domestication on humans is as simple as saying: 'everything.' Although such brevity is hardly informative, it surely contains a kernel of truth. All that we are, and all that we are to become, can be traced to the capture, taming, and eventual subjugation of our fellow animal species. Nevertheless, one can, and should, take some time and space to illustrate this sweeping conclusion with a few examples.

No example may be more powerful in demonstrating the impact of animal domestication on people than the origin stories of some of our oldest cultures. For example, it is in the Vedas, the originating sacred texts of Hinduism where cattle, sheep, horses, and goats play important roles in the creation of the world and of humanity (Koslowski, 2001). Sheep play a fundamental role in the imagery of Judaism and early Christianity. In these examples, one can see that the domestication of animals was not only a technical achievement, but is also imbued with a fundamental contribution to the origin stories of our societies. Apparently, the domestication of animals was so important that these societies viewed their very origin as inextricably linked to the animals in their care and on whose performance their survival was invested (Anderson, 1998; Bulliet, 2005). Therefore, it was that for much of our society's history we viewed the domestication of plants and animals as an unalloyed good. It was this process that has led us to our advancing technology and science, to expand our political and legal organization, and have led us to a comfortable, and civilized, way of life. How could the domestication of animals be anything but a cherished and valuable step on our path to success and personal fulfillment? However that view was to change.

With the advancing discoveries of archeologists and anthropologists, a more nuanced view of the impact of domestication began to take hold. Indeed, by 1987 an article by Jared Diamond could easily proclaim, in the popular science press, that agriculture was "the worst mistake of the human race" (Diamond, 1987). How did this transformation of ideas take place? What in the historical record forced us to move from viewing domestication, and thus agriculture, as an unaltered good to a process suspected of exacerbating the worst of our darker angels (Weisdorf, 2005)?

In broadly described terms, we more clearly see the impact of domestication on our food production as having led to several changes in our societal structure and our biology: an increased exposure to infectious agents, the development of technology, the creation of political organizations and structures, the advent of writing and a change in the natural selection pressures on human evolution. Several of these topics are dealt with in vivid detail in Prof. Diamond's Pulitzer Prize winning book, Guns, Germs, and Steel (Diamond, 1997). In that text, expanding on his earlier article on the 'mistake' of agriculture, Diamond outlines the impact that domestication of large mammals had on human beings and our social/governmental arrangements. To cover this briefly, humans spent hundreds of thousands of years living as hunter/gatherers, consuming a diverse diet of plants and animals. However with the development of domestication, humans became less nomadic and less dependent on gathered foodstuffs. The usually more abundant food supply, at least initially, of domestication led to an expansion of the population, and with it the attendant need to coexist and cooperate across family boundaries to clans and tribes, and eventually to the growth of nation states. Thus, do we see a line connecting the domestication of animals with the growth of government, and with it the growth of class distinctions. And it is in the growth of class, whether determined on economic, political, gender, or ethnic lines, that anthropologists have transitioned to a more balanced and complex view of the domestication of plants and animals (Price, 1995; Zeder, 2006b).

As with other components of this article, addressing the impact of animal domestication on our species would take shelves of books. Here attempt is made only to highlight a few areas of interest and impact; and in that light expect to see some of what this complex invention has done to change our societies, our view of ourselves, as well as how this process has impacted our own biology. In any of the examples that might be considered, it is usually observed that the impact is balanced, and in many ways nuanced by our present economic and political circumstances. That there has been an impact is not for debate. The interpretation of that impact, for 'good' or for 'bad,' may depend on the place from which one takes their view. For example, it is clear that the growth in food supply provided by domestication and agriculture eventually lead to increases in population size and concomitant changes in political arrangements. One need only reflect on the imagery sculpted into Tutankhamun's sarcophagus. In one hand the pharaoh holds a grain flail and in the other hand a sheep crook. Symbols of sustenance and government authority, their origins are deeply embedded in the domestication of plants and animals. How we choose to view that control, as the generous husbandry of a protective shepherd or the onerous treatment under a subordinating ruler may say more about our views of government than our views on the invention of domestication. Consider another example of how domestication of an animal species changed the organization of human society; consider the example of the horse.

Much of what one thinks of the impact of the domestication process, and its impact, relies on varying degrees of speculation. After all, early domesticators did not provide a written record of their successes, failures, or insights. However there are footprints of this process and that has moved our understanding forward. However, there are instances, rare perhaps, where first person, or nearly so, accounts of the impact of the domestication process has been witnessed and if not completely recorded, more recently observed. Such an example would come from the impact of the domestication of the horse, and of horseback riding on a culture previously without this technology. Specifically, one can consider the introduction of horses to the native people of the North American plains.

Though horses evolved on the North American continent, they were extinct by the time Europeans arrived. Why horses were extinct is the subject of some debate (Grayson, 2007) (i.e., a natural extinction or hunted to extinction), but extinct they were. However by the late-seventeenth century, in the Southwestern United States, horses were reintroduced by European colonists. This relatively recent acquisition of horses, especially the impact of horseback riding, has been, all things considered for events occurring between 1680 and 1750 AD, reasonably well documented (Ewers, 1955). As a result, one can visualize the primary and secondary effects that the use of domesticated animals had on early societies. In the instance of horses, there are several obvious uses to which this animal can be put: a new food resource, a power source for bulk transport including long-distance transport of people and goods, a mount for the purpose of hunting other species of wild animal (e.g., bison) and, if necessary, a mount for war against neighboring bands and tribes. In each of these uses, there are obvious and documented outcomes. Chief among them would be a tool to make life on the grassland plains more sustainable and reliable (Catlin, 1973). This, in turn, would lead to an increase in population size for the established social group and an opportunity for accumulation of wealth. Moreover, that accumulation can lead to differentiation of social class and all the attendant consequences such distinctions bring (Ewers, 1955).

The use of horses in the transportation of goods, including the use of this animal as a mount, dramatically increases the territory exploitable by the horse-adopting societies (Krader, 1955). Of course, an expansion of territory simultaneously expands trade and wealth distribution, leads to the development of new community social structures, and any concomitant conflict over the resources provided and exploited by this territorial expansion. Moreover, any conflict over territorial resources will certainly place a decided advantage in the military power provided by horse-mounted warriors (Lauwerier and Hessing, 1992).

This drama has been played out in many locations in North and South America as a result of the colonization of these continents by horse-owning Europeans. Projecting these outcomes and observations to the first societies of the Eurasian steppes is obvious (Levine, 1999). As horse domestication proceeded, and evolved into horseback riding, the fundamental interaction of communities changed dramatically, sometimes peacefully and at other times erupting into open conflict. Interestingly, that conflict has its remnants in the games of today. The national sport of Afghanistan, buzkashi, originated with their horseback riding ancestors with all the attendant maneuver and strategy of mounted cavalry.

This is just one example of how horses impacted the development of early-adopting societies. What we see is how this new invention facilitated actions, emotions, and desires already existent in these groups. Like any invention, the domestication of animals has intended and unintended consequences, both of which played important roles in the evolution of the human communities that adopted this technology.

Beyond the social impacts of domestication, it is also worth considering, if only briefly, the biological impacts of domestication on our fitness and survival. Though the exploitation of plants and animals as a stable food source may have led to an initial expansion of population size, archeological evidence from sites around the globe tell a consistent story of changes in lifespan, stature, nutritional deficiencies, and increased rates of infectious disease (Goodman *et al.*, 1984; Rathbun, 1984). The list of maladies afflicting societies that chose the path of agriculture quite naturally leads one to ask why, "what were they thinking?" Reviewing the paleopathology of early agricultural communities reveals a picture of a society 'pushed' into agriculture, rather than a society 'pulling' itself to a new paradigm. What the archeological record reveals, time after time, site after site, is that the adoption of agriculture extended over a considerable frame of time, interrupted by fits and starts of cultivation and a return to hunting/gathering.

The record of human survival, measured in bone lengths, age of death, and evidence of pathology tell a story of reduced health and longevity in societies engaged in early adoption of agriculture (Armelagos *et al.*, 2005). Though animals can be a

source of agricultural power, and of high-quality protein, this does not seem to have translated to all members of the community. The archeological record suggests that food diversity was reduced, workload and labor increased, and in the case of animals, exposure to new infectious agents all contributed to a dramatically altered quality of life (Armelagos *et al.*, 2005; Diamond, 1997).

This consistent story of the hardships of the domestication process calls into question the 'why' of continuation. One can only speculate, but this long process seems to support the claim, that once a society embarks on the journey to cultivation of their food, there is no retreat to their former model of gathering wild plants and hunting wild animals. For, as these communities transformed their environment so as to be suitable for farming, they simultaneously removed their opportunity to return. Their lot with agriculture had been cast. Cultivation of selected plants required some modification, even destruction, of the natural habitat of other plants and hunted animals. Once changed, the objects of their hunting and gathering had disappeared. It seems a very inauspicious way to begin the journey to today's technologically advanced globally connected society. Nevertheless the record of the past, held in our stories (Koslowski, 2001) and the remnants of pathology in our ancestor's remains, points to an impact of animal domestication that is often free of any obvious benefit beyond simply crossing the hurdles of daily survival. The growth of zoonotic disease alone is enough to question any lasting benefit from the domestication of animals (Armelagos *et al.*, 2005).

The legacy of the impact of zoonotic disease is seen in so many places, in our politics and language. As Prof. Diamond extensively documents (Diamond, 1997), the transmission of disease from animal-owning Europeans to nonanimal-owning North and South American natives changed the maps of the New World. To list only a few examples, the milk, hair, and skin of domesticated animals transmit anthrax, Q fever, brucellosis, and tuberculosis. Add to that partial list food poisoning, parasitic infections, and other water borne diseases, and the common problems of animal agriculture today that must surely have devastated early societies setting out to adopt this technology. Our language still reflects this tie to our domesticated animals. Preventive medicine for many infectious diseases includes the use of vaccines, a word with its roots in *vaca*, Latin for cow.

This association of disease prevention and our domesticated animals derives from the discovery of the British physician Edward Jenner, who observed that people who worked with cattle did not contract smallpox. As is known now, people who worked with cattle were no doubt exposed to cowpox, a disease with far less severe symptoms than smallpox but one that apparently bestows immunity from this dreaded zoonotic scourge. The term vaccination, used by Jenner, means 'from cows,' and so it is that the process of animal domestication, beyond providing the power behind early agriculture or a reliable source of food and fiber, also altered elements of our biological adaptation to the environment. Altering our lifespan, changing our height and exposing us to unfamiliar pathogens has each left its mark on our history as a species. However, the domestication of animals has also altered, and indeed driven, our evolution as a species. Though the time span since the domestication of cattle is relatively short (between 7000 and 8000 years), there has been a demonstrable change in our genome, as evidenced by the recent work on lactase persistence in human populations associated with adult milk consumption (Tishkoff *et al.*, 2006).

Like all mammals, human infants use milk as their sole source of nutrients, gradually taking on solid food until weaning. During infancy, with rare exception, lactose, a disaccharide of glucose and galactose, is broken into its two simple sugars by the enzyme lactase-phlorizin hydrolase (LPH) in the small intestine (Swallow, 2003). The capacity to activate LPH and digest lactose typically declines after weaning. However, some individuals maintain this capacity into adulthood, a trait called 'lactase persistence.' Lactase persistence is a dominant Mendelian trait. The fascinating element of this trait, however, is the changing frequency of this dominant allele from one human population to the next. That is, nonpastoralist populations in Asia and Africa have a very low frequency of this allele; approximately 1% in China and between 5% and 20% in West Africa (Durham, 1992; Swallow, 2003). However in populations that rely on milk as a food source into adulthood, populations with the practice of keeping cows, the allele for lactase persistence jumps to more than 90% in places like Denmark and Sweden (Durham, 1992; Swallow, 2003). Other populations and ethnic groups in Africa, with a culture of cattle and milk consumption into adulthood also carry the persistence allele in high frequency (Tishkoff *et al.*, 2006). What we see demonstrated here is the presence of a very strong selective sweep, one that has dramatically altered human evolution in a relatively short span of time. Domestication of animals has not just changed how we live and how we eat, it has fundamentally altered our very biology.

Conclusion

For most of our time as a species, whenever that may have begun, human beings lived in ways little different from our animal relatives and neighbors. However eventually we began to live in groups and social settings where we began to feel different, feeling distinct, and separate from the other animals. Eventually that feeling would change, and as human social groups evolved we began to question our relationship to, and with, the animals around us. That feeling of distinction finally brought us to the task of changing some of these animals to fit our needs and expectations; to move them from wild animals to our now close domestic 'partners.' What the future will hold for our mutual relationship can only be guessed. What remains certain is the importance this process has played in our lives and culture.

Glossary

Archaeobotany The identification and analysis of botanical remains found in archeological investigations. The remains can be subdivided into macroremains (identifiable to the naked eye) and microremains (require the use of a microscope). Among macroremains are seeds and pods. Microremains include pollen grains and subcellular structures like starch grains and phytoliths (silica deposit inside plant cells). The shape of microremains can be diagnostic of the identity of the plant material. The conservation of archaeobotanical remains can be favored by certain environmental conditions (like dryness or excess water).

Centers of agricultural origins Agriculture started in multiple locations in the world some 10 000 years ago. These locations (where crop domestications took place) are distributed in some 10 areas generally between 30° northern latitude and southern latitude. They tend to occur in areas with higher levels of biodiversity.

Domestication Evolutionary process driven by natural and human (whether conscious or unconscious) selection applied to wild plants or animals and leading to adaptation to cultivation and consumption or utilization. Domestication can be complete, whereby organisms become entirely dependent on humans for their continued existence or can be partial or incipient, whereby they still reproduce independently of human intervention.

Domestication syndrome A set of morphological, biochemical, and physiological traits that distinguishes domesticated plants or animals from their wild progenitor. These traits depend on the life history (annual vs. perennial) and reproductive system (outcrossing, selfing, and vegetative reproduction). Traits affected include dispersal of propagules (e.g., seed shattering and pod dehiscence), seed dormancy, growth habit, diversity of harvested parts (size, shape, and color), flowering response to environmental cues (temperature and day length), organoleptic qualities (taste, texture, and toxicity), and any other traits affecting harvested product use (e.g., fiber quality).

Molecular markers Markers are traits with a simple inheritance (like Mendel's characters). Molecular markers are based directly or indirectly on deoxyribonucleic acid (DNA) sequence variation. Indirect molecular markers are proteins, such as isozymes (enzymes of the basic metabolism, which can be distinguished by their electric charge) and seed proteins (which can be distinguished by their size). Direct molecular markers include RFLP, RAPD, AFLP, etc. markers (which can be distinguished by the DNA fragment sizes). Increasingly, the actual DNA sequence is used to distinguish among individuals and trace back their ancestry.

Quantitative trait loci Locus controlling a quantitative trait that differs from a Mendelian trait (or marker locus: see Molecular marker) in that it does not exhibit clear-cut segregation classes because the trait is controlled by more than one gene or is subject to environmental effects or a combination of the two. These are often measured traits (e.g., yield and seed weight) or counts (number of seeds or days to flowering). Because of the lack of segregation classes, the inheritance is analyzed by correlating markers with the expression of the trait in segregation populations resulting from the cross between two contrasting parents.

Taphonomy The science of fossilization. It studies the factors that favor or hinder the formation of fossils.

Introduction

The evolutionary lineage leading to the modern human species (*Homo sapiens*) has been marked by several key inventions, such as the development of increasingly sophisticated tools (Stout, 2011), the mastery of fire (Alperson-Afil and Goren-Inbar, 2010; Berna *et al.*, 2012; Twomey, 2013), the acquisition of writing (Houston, 2004), and the current digital revolution. Among these inventions is agriculture or the transition from hunting-gathering (HG) to the cultivation of crops and tending of animals. This transition initiated a change that cannot be overestimated in all aspects of life on the earth, including the biological and physical environment and, obviously, also the way of life of humans. It is, therefore, not surprising that this transition has been called the Neolithic Revolution.

The signs of the changes brought about by the momentous introduction of agriculture are numerous. For example, many famous 'natural' landscapes on the earth are actually agricultural landscapes: the rice terraces of Yunnan in China, the rolling, cypress-studded lands of Tuscany in Italy, and the big-sky, luminous plains of the Palouse in Northwest United States. Thirty-eight percent of total land area is now devoted to agriculture, making it currently the single most important land use. For example, forests (most of which are subjected to some type of anthropic exploitation) only account for 30% of the land area (FAO, Land use database).

Among the changes that were more or less concurrent with the origination of agriculture were sedentism (as opposed to nomadism) and the appearance of villages and ultimately cities, the introduction of ceramics, the transformation of more egalitarian societies into more hierarchical ones, a stronger division of labor by the addition of nonfood production related occupations, and, later on, the introduction of writing. The actual sequence and order of these technologies is still being disputed and may diverge in different regions where

 doi:10.1016/B978-0-444-52512-3.00231-X

agriculture was initiated. Ultimately, the transition from HG to agriculture was a precursor and a necessary condition for the eventual appearance of civilizations. The sequence of events subsequent to the initial transition to agriculture is beyond the scope of this article but is the subject of intensive, long-term studies (e.g., Maisels, 1993; Price and Bar-Yosef, 2010; Kuzmin *et al.*, 2011). As stated by Diamond (1997), "plant and animal domestication meant much more food and hence much denser populations. The resulting food surpluses … were a prerequisite for the development of settled, politically centralized, socially stratified, economically complex, technologically innovative societies."

Agriculture has been for some time and is still the main source of food, fiber, and feed for humanity. So far, it has been able to keep up with the tremendous growth in population. It has been estimated that the total human population at the time of the Neolithic Revolution was approximately 6 million people (Livi-Bacci, 2012), which now amounts to 7 billion (World Population Clock, US Census Bureau), with a nearly certain prospect of a further increase of 2 billion by 2050 (United Nations, Department of Economic and Social Affairs). The current hunger episodes are not due to insufficient production but other factors affecting food security (FAO, The State of Food Insecurity). Nevertheless, the dominance of agriculture as a human activity has come at an ecological price, which includes habitat destruction, reduction in biodiversity both of natural and agricultural ecosystems, widespread contamination with chemicals of agricultural origins, such as fertilizers and pesticides, and a significant part of the emissions of greenhouse gases.

It is in this broader context that domestication of crop plants (and farm animals) has operated, not only as a component of the adaptive process to which cultivation (or captive rearing) has subjected them by humans but also more broadly as part of the Neolithic Revolution that included the transition from HG to agriculture.

The Concept of Domestication and the Domestication Syndrome

Domestication is, in essence, an evolutionary process of selection for adaptation to changed environmental conditions, as plants are not only consumed but also actively cultivated. Cultivation is a necessary condition for domestication to take place. The selective forces that act on plant populations in the original natural environments are to a great extent different from those in the subsequent cultivated environments. In natural environments, strong intra- and interspecific competition exists among plants for light, water, and soil nutrients. In contrast, agroecosystems are characterized by less competition, even in well-known, diverse arrangements like agroforestry (Leakey, 1998; Perfecto and Vandermeer, 2010) and gardens (e.g., Ban and Coomes, 2004; Buchmann, 2009). This reduced competition is then converted into higher productivity for harvested organs (e.g., grain, leaves, roots, etc.) through modified partitioning of photosynthates and a higher harvest index (ratio of harvested biomass to total biomass).

A second major difference between natural and cultivated environments is the need for developing a more efficient production system, in terms of biomass per unit of surface and time. The overall goal has been to increase the harvested biomass although decreasing the total effort necessary to harvest this biomass. Hence, several traits have been selected to achieve this goal. These traits include: (1) loss of seed dormancy, which led to more uniform stands at planting; (2) a more compact growth habit, with reduced branching and shorter branches, which reduces intraspecific competition and makes harvest more synchronous; (3) a tendency for reproduction to evolve from outcrossing to inbreeding to vegetative propagation, which makes reproduction less dependent on abiotic and biotic factors; and (4) reduced or loss of seed shattering, which limits grain losses at harvest.

Third, humans also exert an important selective role not only as farmers but also as consumers of their production, irrespective of whether it is for food, feed, or fiber. A key aspect here is the attraction of humans for novelties, such as new seed and fruit colors or shapes, which has led to the striking morphological diversity in some crops, such as developmental differences in cabbages (*Brassica* spp.: red cabbage, Brussels sprouts, cauliflower, etc.); seed color, size, and shapes in certain legumes (*Phaseolus* sp. and *Vigna* sp.); and fruit size, shape, texture, and color in the Rosaceae (e.g., apple: *Malus* sp.; pear: *Pyrus* sp.; and cherry and plum: *Prunus* sp.). Generally, domestication has led to an increase in the size of the harvested organs, irrespective of whether they are roots, leaves, fruits, or grains. Increases in size can sometimes by remarkable as they can reach a $10x$–$20x$ difference between wild and domesticated types. Plants generally contain toxic substances that fulfill several functions like protection against diseases or pests. During domestication, the concentration of these compounds has generally decreased in all or at least part of the domesticated gene pool, as shown, for example, by the reduction in cyanogenic glucosides in cassava (Bradbury *et al.*, 2013) or lima bean (Vanderborght, 1979).

The existence of these sets of correlated traits that are characteristic of domesticated plants and show some degree of consistency among different, even unrelated, crops led Hammer (1984) to call them 'domestication syndromes.' Such syndromes are generally applicable to more strongly domesticated plants; however, there are sometimes important differences among crop plants, depending on their life history and reproductive mode (Harlan *et al.*, 1973; Smartt, 1990; Ladizinsky, 1998; Hancock, 2004; McKey *et al.*, 2010, 2012). Perennial plants, such as fruit and nut trees or vines, often show more limited differences between wild and domesticated types because of their extended juvenile phase, long life cycle, high gene flow levels, and potential for vegetative reproduction (Miller and Gross, 2011). For example, the main domestication trait in grape vine is the evolution from a diecious (separate male and female individuals) reproduction to an autogamous reproduction, made possible by hermaphroditic flowers (with both male and female reproductive organs). This change is controlled by a single locus (Battilana *et al.*, 2013). Thus, in general the domestication syndrome of perennial crops consists of fewer differences between wild progenitor and domesticated descendant (Pickersgill, 2007). The expression of constituent traits is also often limited. For a given crop, there may be different domestication syndromes, depending on the local production circumstances. For example,

one could envision a different domestication syndrome for maize grown for grain (as is currently the case) or for its vegetative matter as feedstock for biofuels. The latter could involve a more branched plant type that increases the production of stems and leaves rather than grain. Meyer *et al.* (2012) provided an extensive overview of the broad range of traits characterizing domesticated plants. Dempewolf *et al.* (2008) provided a discussion on the level of domestication.

Finally, the constituent traits of the domestication syndrome are often deleterious in the wild. For example, more compact growth habits and loss of spontaneous seed shattering reduce the fitness in natural environments because they limit competitiveness with the surrounding vegetation and reproductive ability, respectively. Although they are selected against in the wild, the opposite is true in agricultural environments.

Where Did Domestications Take Place?

The domestication of crops, as an invention, is embedded in the origins of agriculture. The transition from HG to agriculture has taken place in multiple regions of the earth, remarkably at about the same time approximately 12 000–10 000 years ago in the aftermath of the last (Wurm) ice age. The actual causes for this transition are poorly understood and therefore both the location and timing of the transitions can only be investigated empirically using a combination of information from different fields, each with their strengths and weaknesses.

The main fields contributing knowledge about the origins of agriculture have traditionally been archeology, biology, linguistics, and history as proposed by de Candolle (1882) in the nineteenth century. Since then, a broad range of scientific fields have been applied to solve the puzzle of agricultural origins. Archaeobotany seeks to describe archeological remains of crop plants and their wild progenitors from Neolithic sites. Of particular interest is the transition in the archeological record from cultivation of wild plants (predomestication cultivation) to the cultivation of actual domesticates. Some key traits have been identified, mainly pertaining to seed shattering in cereals, such as wheat and barley (Hillman and Davies, 1990; Tanno and Willcox, 2006; Fuller and Allaby, 2009). An additional advantage of archeobotanical remains is that they can be dated by ^{14}C accelerator mass spectrometry, which allows direct dating of the remains rather than indirect stratigraphic dating previously practiced with ^{14}C dating (Smith, 1989, 1997; Kaplan and Lynch, 1999; Benz, 2001; Pinhasi *et al.*, 2005). A disadvantage of archeobotanical approaches is that they are limited to the available archeological sites, which may not be representative of the geographic distribution of early agriculture and in many regions are limited in number.

Genetic evidence is based primarily on the study of contemporary wild and domesticated populations of plants. An important element is to determine the identity of the wild ancestor of each crop. This has been accomplished for most crops, first through artificial hybridizations that determine the viability and fertility of progenies between crops and putative wild ancestors (Harlan and de Wet, 1971). Because domestication took place only 10 000–12 000 years ago at most, there has been limited differentiation between a crop plant and its wild ancestor, one expects normal viability and fertility in their cross in most cases, with the exception of polyploid series, such as wheat. In the latter crops, crosses involving different ploidy levels usually do not yield viable or fertile progenies in spite of the close genetic relationship expected from ancestor–descendant relationship.

Additional analyses involving molecular markers can then refine the identity of the crop ancestor. All molecular markers are ultimately based on deoxyribonucleic acid (DNA) sequences, irrespective of whether they are proteins, such as enzymes (allozymes) and seed storage proteins, or DNA sequences themselves. Because of advances in DNA sequencing technologies, plant populations are increasingly being characterized by sequencing directly (genotyping by sequencing) (Doebley, 1992; Gepts, 1993; Burke *et al.*, 2007; Gross and Olsen, 2010; Olsen and Wendel, 2013). These analyses, akin to paternity tests, reveal a minimum number of domestications and in some cases also a more defined putative region of domestication within the overall distribution area of the wild ancestral form. Recent examples of this capability include the identification of putative domestication areas for crops in the Mesoamerican center of agricultural origins, such as maize (*Zea mays*; Matsuoka *et al.*, 2002), common bean (*Phaseolus vulgaris*; Kwak *et al.*, 2009), and pepper (*Capsicum annuum*; Loaiza-Figueroa *et al.*, 1989), in different areas of the Mexican territory. This polycentric process of assembly of cropping systems in the Mesoamerican center is mirrored in other centers of agricultural origins like Southwest Asia ('Fertile Crescent') and China (Fuller *et al.*, 2012; Riehl *et al.*, 2013; Cohen, 2011; d'Alpoim Guedes, 2011).

Two potential confounding factors operate when attempting to determine an area of domestication. First, gene flow both within the domesticated types and between domesticated and wild types can obscure the local relatedness relationships. For example, maize (*Z. mays* var. *mays*) was domesticated from lowland teosinte (*Z. mays* var. *parviglumis*), but the close relationship between domesticated maize and highland teosinte (*Z. mays* var. *mexicana*) is due to gene flow (van Heerwaarden *et al.*, 2011). Common bean, a predominantly self-pollinated species, nevertheless shows evidence of low but detectable levels of gene flow between wild and domesticated types (Papa and Gepts, 2003; Papa *et al.*, 2005, 2007; Payró de la Cruz *et al.*, 2005; Zizumbo-Villarreal *et al.*, 2005).

Second, there is possibility that the distribution of the wild relative has changed since the initial domestication process. Contemporary wild progenitors are the immediate descendants of the wild types that were domesticated and genetically closest to the original types that were domesticated. They are, therefore, the plant material of choice when studying domestication (Ross-Ibarra *et al.*, 2007). Existing climate models combined with species distribution models may be used to retrospectively estimate the original distribution of the putative ancestral type.

Occasionally, genetic analyses target ancient DNA contained in archeobotanical remains (Jaenicke-Després *et al.*, 2003; Roullier *et al.*, 2013). Although these experiments represent a laboratory tour de force to obtain data from degraded

DNA, their scope is generally limited, however, by the small sample size of the analyses so far, thus limiting the inferences that can be made. Linguistic analyses also contribute to the determination of the area of domestication. The existence of words designating a crop, its product, or tools related to the crop, in native languages provide an additional indication of the importance of the crop. More recently, paleobiolinguistics has reconstructed words in precursors of modern languages (protolanguages), dated them based on lexical similarity, and located the homeland center based on lexical diversity (e.g., common bean, Brown, 2006; cassava, Brown *et al.*, 2013b; and pepper, Brown *et al.*, 2013a). A question associated with the linguistic approach – and other approaches as well – is the antiquity of the evidence it can uncover.

Based on these analyses, **Figure 1** shows a sample of crop domestication origins. Several of these centers of origin are fairly well circumscribed, such as the Mesoamerican, Southwest Asian, and Chinese centers. Others cover a much broader territory, such as the South American, African, and Southeast Asian centers. In all cases, however, recent archeobotanical and genetic data suggest that individual crops were domesticated in different areas within each of these centers (Fuller *et al.*, 2012; Riehl *et al.*, 2013; Cohen, 2011; d'Alpoim Guedes, 2011; Clement *et al.*, 2010; Piperno and Pearsall, 1998; Piperno, 2011). For example, maize and common bean were domesticated in different watersheds in western Mexico but were eventually united postdomestication into the milpa ('three sisters') cropping system with squash (Matsuoka *et al.*, 2002; Kwak *et al.*, 2009; Zizumbo-Villareal and Colunga GarcíaMarín, 2010; Zizumbo-Villarreal *et al.*, 2012). Einkorn, durum, and bread wheat were domesticated in different areas of the Fertile Crescent or adjacent regions (Riehl *et al.*, 2013, Willcox, 2013). Barley was domesticated not only in the Fertile Crescent but also further east in Central Asia (Morrell and Clegg, 2007) and Tibet (Dai *et al.*, 2012). In China, there may be at least two domestication areas (Bettinger *et al.*, 2010; Cohen, 2011), one primarily in the Yellow River basin, where millets (broomcorn millet (*Panicum miliaceum*) and foxtail millet (*Setaria italica*)) were domesticated, and the Yangtze River basin, where Asian rice (*Oryza sativa*) was domesticated.

This geographic analysis can be complemented with an ecological analysis through the identification of the major biomes in which crops originated (Harlan, 1992). A biome is a major terrestrial environment characterized by its overall climate (mainly temperature and rainfall), vegetation, and fauna. Some 10 biomes have been described, including tundra, taiga (evergreen coniferous forest), temperate deciduous forest, grasslands (prairie or steppe), deserts, Mediterranean or chaparral, tropical savanna, tropical deciduous forest, and tropical evergreen forest. For each of these biomes, one can

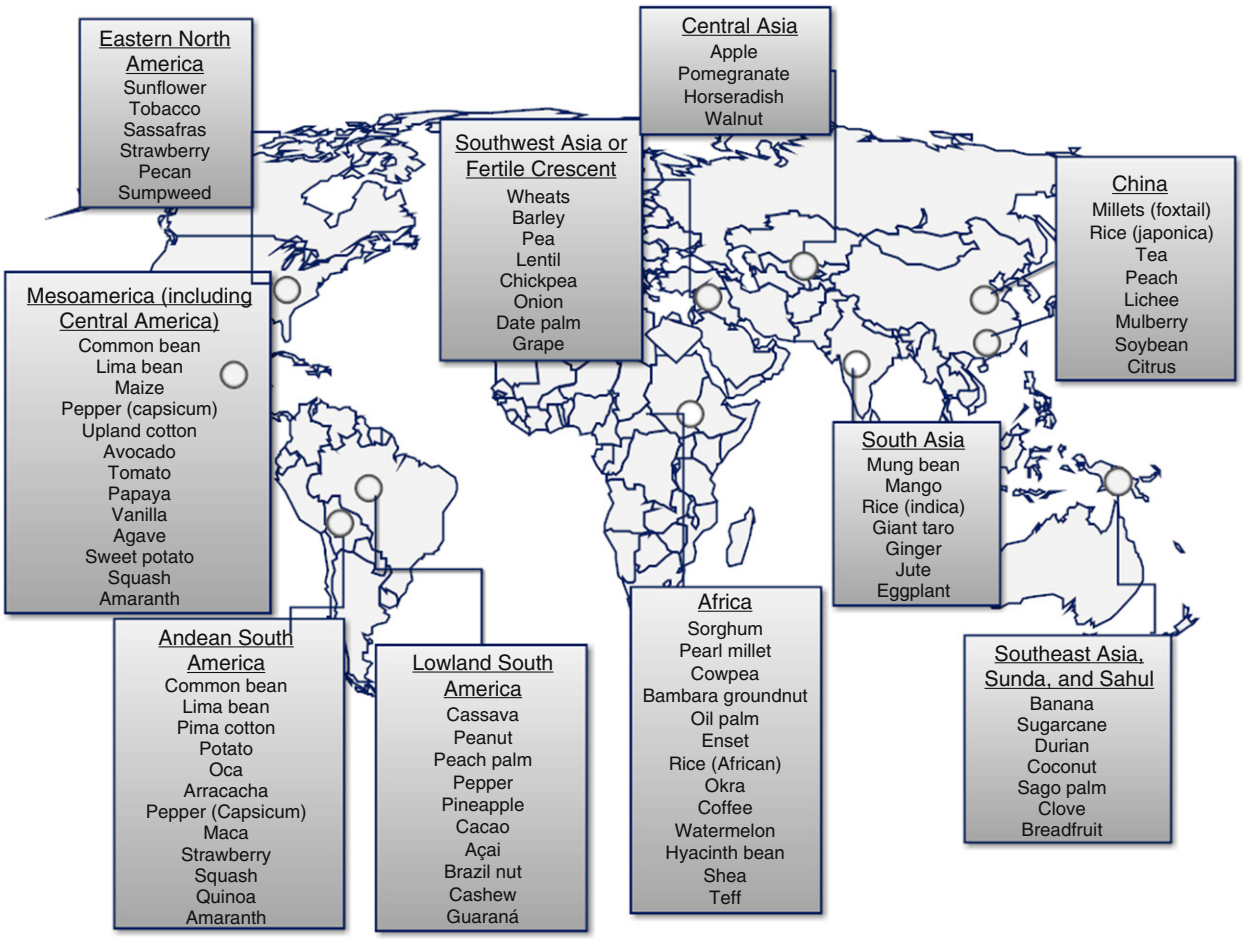

Figure 1 Selected centers of agricultural origins and their respective crops.

then assess to what extent they have played a role in the origins of agriculture and crop domestication. Such an analysis reveals that several crops originated in two biomes, the Mediterranean and tropical savanna biomes. Among crops domesticated in the Mediterranean biome are those from the Fertile Crescent, such as wheat, barley, lentil, chickpea, and pea. Crops domesticated in the savanna biome (and adjacent dry tropical forest) include crops such as maize, common bean, rice, cassava, and peanut. These two biomes share the characteristic of a long dry season, whether during the summer for the former or the winter for the latter (monsoon-type of climate). The dry season may have been an impetus toward cultivation because of the increased need to develop a store of food, irrespective of whether they are grain or roots.

Domestications are not exclusive to the Mediterranean or tropical dry savanna and forest biomes. Other environments have contributed crops as well, such as highland environments (e.g., coffee in the Ethiopian plateau; several root crops, including potato in the Andes Mountains). Coastal areas have contributed coconut, beets and more recently sugarbeets, and cotton. Temperate forest may have contributed fruits and nuts, such as apples, pear, cherry, and walnut. Tropical rain forests were most likely the home of sugarcane, banana and plantain, mango, and cacao.

Centers of domestication tend to occur in areas of higher biodiversity or biodiversity hotspots (Gepts, 2008). Thus, actual or prospective farmers have been opportunistic in recognizing potential crop plants by domesticating them from local biodiversity, wherever they were located. In this regard, it is perhaps not surprising that certain species or groups of related species have been domesticated multiple times. For example, there are five domesticated *Phaseolus* bean species, two of which – common bean and lima bean (*Phaseolus lunatus*) – have been domesticated twice, in Mesoamerica and in the Andes (Gepts, 1998; Serrano-Serrano *et al.*, 2012; Andueza-Noh *et al.*, 2013). Three other domesticated *Phaseolus* species – runner bean (*Phaseolus coccineus*), year bean (*Phaseolus dumosus*), and tepary bean (*Phaseolus acutifolius*) – were domesticated in ecologically different environment (Freytag and Debouck, 2002), reflecting a possible choice on the part of farmers to select different domesticates rather than adapt a single domesticate to a broad range of environments. Other examples are *Capsicum* species (five species domesticated in different areas of Mexico, Central America, and South America; Pickersgill, 2007), cotton (four species domesticated, two in the Old World and two in the New World; Wendel *et al.*, 2009), and wheat (three species domesticated in and around the Fertile Crescent; Willcox, 2013).

When and How Quickly Did Domestication Take Place?

One of the remarkable observations concerning the origins of agriculture is that most origins trace back to a similar period, approximately 11 500–8 000 BP (Price and Bar-Yosef, 2011 and other articles in the same special issue). This period coincides with the end of the last Ice Age. This may suggest that climate change may have played a role in the transition from HG to agriculture, either because the warming temperatures may have been more favorable for cultivation or may have increased the length of dry seasons. In addition, a climatic singularity may have played a role. It has also been suggested that there was an increase in CO_2, which may have stimulated plant growth around that time (Sage, 1995), or that the climatic conditions became more stable thereby facilitating selection for adaptation during the domestication process (Richerson *et al.*, 2001). However, alternative explanations can be offered. For example, the different groups of humans initiating the practice of agriculture did so because they had reach similar levels of cultural development, including knowledge of food plants and their respective harvest and processing methods. An additional feature of this transition is that climate change did not proceed linearly toward a warmer and drier state. Following an initial, brief warming after the last age, there was a reversion – the Younger Dryas – when cold and dry conditions returned from the preceding warmer/wetter Bølling–Allerød interstadial between the Pleistocene and Holocene eras. The Younger Dryas lasted approximately from 13 000 to 11 500 BP years (Balter, 2010). It is thought to have been one of the factors leading hunter-gatherers to start cultivating plants, not only in the Fertile Crescent (but for opinions to the contrary, see, e.g., Willcox *et al.*, 2008), but also to varying degrees in other areas involved in the origins of agriculture (Bar-Yosef, 2011).

Although there is some variation in the earliest dates for each of the centers of origin, there is also great variation in the abundance of archeological sites among centers. The Fertile Crescent is generally considered to be the most intensively studied center of agricultural origins. One is more likely to find older when the number of sites increases. Another factor influencing the antiquity of archeobotanical remains is the nature of the remains. Macroremains (e.g., whole seeds) are generally less likely to survive undamaged for a long time. Hence, they will generally be younger than microremains (e.g., phytoliths or starch grains). For example, the oldest remains for common bean and maize are starch grains (Piperno and Dillehay, 2008; Piperno *et al.*, 2009). Thus, when comparing the domestication age of different crops, the type of remain and the taphonomic parameters that affect their survival should be taken into account (Allison and Bottjer, 2011).

The duration of the process of domestication has only recently drawn attention, in part because of the recent discovery of sites that harbor a mix of wild and presumably domesticated remains, principally in the Fertile Crescent and China (Fuller *et al.*, 2009, 2012). Two traits have been studied principally: seed shattering (in cereals only) and seed size (in cereals and other crops). Seed shattering in cereals takes place because of the presence of a brittle inflorescence axis (also called rachis). A brittle rachis can be recognized because of the smooth break area where the seed developed on the rachis, in contrast with the rough breakage area caused by mechanical threshing to release seeds from the nonbrittle rachis. Because of the qualitative nature of the trait (presence or absence of abscission scar) and the clear segregation classes, there are no environmental effects on the trait and therefore limited ambiguities in determining the domesticated status of the remains (aside from potential developmental differences). Thus, this anatomical diagnostic trait makes it possible to follow the progress toward full domestication ($\sim$100% of remains in the

domesticated category) in any given archeological site. For seed weight, one or more of the dimensions of the seed are measured. Based on observations on contemporary wild and domesticated seeds, one can determine a threshold beyond which a seed can be considered domesticated as opposed to a wild-type seed. A complicating factor here is that seed size is influenced by environmental conditions (Johannsen, 1909; Harper *et al.*, 1970; Motto *et al.*, 1978). An increase in seed size can, therefore, not be considered automatically as a result of an ongoing domestication process (i.e., a genetic change due to selection) but could also represent an improvement in growing conditions. For example, reduced population densities in wild stands (because of previous harvests) may lead to larger seeds, as does cultivation, even in the absence of selection during domestication. An increase in seed size can potentially be taken as evidence for domestication, but only with the necessary caution.

Several approaches have been followed to estimate the duration of domestication. Empirical approaches involving harvesting of contemporary wild populations of cereals – einkorn wheat (*Triticum monococcum*), emmer wheat (*Triticum dicoccum*), and barley (*Hordeum vulgare*) – as well as mathematical modeling of the frequency of mutant (nonshattering) alleles have shown that with the appropriate harvest method (e.g., use of sickles) could proceed quickly (from 20–30 to 300 generations) (Hillman and Davies, 1990). Factors considered in the modeling experiments were the level of selection intensity and self-pollination, with stronger selection and higher inbreeding levels accelerating the pace of domestication. Thus, it would appear on the face of these experiments that there would be no genetic impediments to a rapid domestication once mutations were present in the wild populations.

Molecular analysis of DNA sequence variation has also provided estimates of the length of the domestication bottleneck. In maize, when taking a domestication duration of at most 2800 years (Eyre-Walker *et al.*, 1998), the bottleneck size was estimated at 3500 individuals.

In soybean, a domestication bottleneck of 3000 year was posited for a founding population of 6000 individuals (Guo *et al.*, 2010), whereas in rice the founding population was only 1500 for a similar duration (Zhu *et al.*, 2007). These estimates are ambiguous, however, because the bottleneck severity depends on both population size and duration of the bottleneck. Thus, estimates of the duration of the bottleneck are dependent on the size of the population of the wild progenitor during the domestication process, which is essentially unknown.

One should also take into account several considerations that can slow down the speed of domestication. First, the source of variation for domestication alleles may determine how quickly domestication could proceed, namely, whether variation originated in existing variation in the wild progenitor populations ('standing variation') or if it originated in *de novo* mutations. Standing variation may have led to faster domestication than reliance on *de novo* mutations; however, it remains to be determined how strong a barrier the appearance of mutations would be, given the large population sizes observed for some wild relatives. Observations in a wide range of organisms and traits have shown that selection for adaptation relies on both standing variation and *de novo* mutations (Durand *et al.*, 2010; Peter *et al.*, 2012; Fu and Akey, 2013; Studer *et al.*, 2011). Second, the modeling experiments assume constant, nonzero selection levels in each generation, which may not have been the case, given that at least in its initial phase, agricultural production may have been a supplementary source of food rather than a mainstay. In some years, there may not have been any cultivation at all and therefore no selection leading potentially to domestication. Third, domestication in most cases is based on multiple traits, which have to be recombined into a single evolutionary lineage. Even if selection for individual domestication traits was taking place in different lineages, ultimately these individual traits needed to be combined through outcrossing among lineages and recombination in the progenies. Aside from the likely chance encounter of lineages, outcrossing (especially in autogamous species) and the concomitant recombination will almost certainly have slowed down, although not prevented the domestication process. Fourth, hybridizations between the wild ancestor and the incipient domestication, a likely occurrence if the two types were sympatric, would have also slowed down domestication by diluting the frequency of domestication alleles and decreasing the expression of the traits they control, given their generally recessive nature (Ladizinsky, 1985).

These considerations, as well as archeobotanical observations, have led to the current proposal that domestication was a drawn-out process taking place over several millennia, generally approximately 2000–3000 years (Allaby *et al.*, 2008; Fuller *et al.*, 2012). This proposal is based on several observations. There is a relationship between the frequency of domesticated phenotypes (e.g., seed size and nonbrittleness) and their age over several sites in the Fertile Crescent and China (Fuller, 2007): the younger the site, the higher the frequency of domesticated archeobotanical remains. Concomitantly, there is an increase in the frequency of seeds of the so-called arable weeds that accompany crop cultivation (Colledge and Conolly, 2010). Finally, the amounts of stored grains also increased around this time and have been deemed to be too large to originate in mere gatherings of wild seeds.

In turn, these new arguments need to be considered with caution. The development of a timeline for domestication based on different archeological sites (e.g., Tanno and Willcox, 2006) introduces a confounding factor, namely, the differential rate of spread or adoption of agriculture. Thus, differences in the percentage of domesticated remains among locations may not reflect the degree of advancement of the domestication process but rather the differential spread or the earlier or later adoption of cultivation of plants. In addition, the presence of weeds may not necessarily indicate the presence of cultivation. The main characteristic of these weeds is their adaptation to disturbed conditions and their ability to colonize these environments. Although plowed fields are disturbed environments, they are not the only anthropogenic environments. Terrains with intensely harvested wild populations or the surroundings of villages could also be a source of arable weed seeds. Thus, the mere presence of these plants does not necessarily indicate cultivation and may lead to an overestimate of the duration of the domestication process. Large amounts of grains in storage likewise is not indicative of harvest from cultivated plots. Several experiments or observations on the production of wild stands of plants, whether

annuals or perennials, suggest high levels of productivity in natural stand of crop wild relatives (CWR) (Harlan, 1967; Hillman and Davies, 1990). The proposed extended predomestication cultivation also needs to be reconciled with a potential push–pull situation related to the cultivation and harvest of wild plants. Cultivation of a wild plant that is unadapted to cultural practices, including planting and harvesting, may not lead to expected yields needed to complement harvests from wild plant gathering. Abbo *et al.* (2011, 2013) showed how harvests of wild pea are very variable and low across location and years, making cultivation for a substantial number of years less likely unless key mutations would be present in these populations to increase yield, such as mutations for reduced seed dormancy after planting and limited pod dehiscence at maturity. However, once this type of mutation is present, domestication could proceed more rapidly as suggested by Tzarfati *et al.* (2013), who showed how the nonbrittleness and free-threshing mutations in emmer wheat (*Triticum turgidum*) reduced threshing time by 30% and 85%, respectively, thus providing an incentive for cultivation of these variants. An important limiting factor may, therefore, be the frequency of mutations pertaining to domestication syndrome traits in wild progenitor populations, combined with gene flow and recombination rates of these different mutations into a single evolutionary lineage.

Overall, the actual duration of the domestication process is still a controversial topic. Although it is probably longer than what the analysis of individual traits suggests, claims for a long predomestication cultivation phase need to be examined with caution and the actual length should be determined more precisely.

A Common Feature among Domestications: Reduction of Genetic Diversity at the Genome Level

A general feature of domestication is the reduction of genetic diversity in the domesticated gene pool compared with the gene pool of the wild progenitor. The amount of reduction depends on the species, its reproductive system, and the molecular marker system used. In general, outcrossing species show a smaller reduction compared with selfing species (e.g., maize: 83% nucleotide diversity retained in domesticated gene pool, Hufford *et al.*, 2012, 2013; rice: 60–65%, Caicedo *et al.*, 2007, or 35%, Zhu *et al.*, 2007; common bean: ~40% each in Andean and Mesoamerican domestications, Bitocchi *et al.*, 2013; soybean: ~60%, Lam *et al.*, 2010). Vegetatively propagated crops also tend to maintain high levels of genetic diversity as illustrated by grape and apple (95% retention of diversity, Myles *et al.*, 2011; Cornille *et al.*, 2013). Techniques of propagation of specific phenotypic variants, such as grafting or cuttings, as well as the role of major genes in the genetic control of individual traits, and the presence of a juvenility period and the long production period in vine or tree crops could have strongly reduced genetic diversity. Nevertheless, gene flow from local wild populations, small-scale propagation, local adaptation to environmental conditions, and consumer preferences could act to maintain high levels of diversity (Cornille *et al.*, 2013).

Domestication has also affected multilocus association as measured by linkage disequilibrium (LD), the nonrandom association of gametes. The nonrandomness can arise from close linkage, in which case LD can be used to map loci controlling phenotypic traits. LD, however, is also induced by other factors, such as population structure induced by geographic isolation, genetic bottlenecks, and reduced recombination. For example, in common bean, which consists of two geographically separated taxa (Andean vs. Mesoamerican), there is much higher LD in a sample including the two taxa (95% of locus pairs in LD) than in separate Andean and Mesoamerican samples (~70%; Kwak and Gepts, 2009). In general, LD increases as a consequence of domestication (e.g., maize: Wright *et al.*, 2005; Hufford *et al.*, 2012; rice: Zhu *et al.*, 2007; soybean: Hyten *et al.*, 2007; sunflower: Kolkman *et al.*, 2007; common bean: Kwak and Gepts, 2009; Rossi *et al.*, 2009; foxtail millet: Wang *et al.*, 2010).

The Genetic and Molecular Basis of the Domestication Syndrome

Although crops and their wild progenitors belong to the same biological species and their divergence was initiated only some 10 000 years ago, they generally show marked morphological and physiological differentiation as a result of the selection for adaptation to human cultivation and consumption for food and nonfood uses. The genetic basis for this profound change resulting in crop plants as are known today has only relatively recently been elucidated. Initially, genetic analyses were conducted on individual traits. The general conclusion was twofold, namely, that most domesticated traits were controlled by recessive alleles at one or two genes, suggesting loss of function mutations (Ladizinsky, 1985). Such studies were generally limited, however, by the lack of information on the location of these genes within plant genomes and their potential linkage. The ability to develop linkage maps with molecular markers of sufficient density and distribution in the crop genome, together with the development of segregating populations resulting from crosses between carefully selected wild and domesticated genotypes, remedied this situation and provided a more complete picture (including linkage information) on the inheritance of the domestication syndrome.

Results from these analyses have led to a series of general conclusions about the architecture of the genetic control of the domestication syndromes across a broad range of crops, mostly annual, herbaceous plants (Gepts, 2004). A first conclusion is that often major, Mendelian genes or quantitative trait loci (QTLs) control individual traits, in addition to genes or QTLs of smaller effect. This observation confirms the single-trait analyses. Second, the phenotypic variation is often mainly due to genetic rather than environmental effects, suggesting high heritability. The first two observations suggest a simple genetic control, which would have facilitated and speeded up selection during the first stages of domestication. Third, in many crops, a subset of the genes controlling the domestication syndrome are linked, at least loosely, on a limited number of chromosomes. The latter situation may have been an advantage in situation where hybridizations take place, either between wild and domesticated types or among

incipient domesticates in the early phases of domestication when lineages with different elements of the domestication syndrome were recombined. Linkage made recovery of parts of the hybridization syndrome easier, although not preventing assembly of the domestication syndrome because of repulsion linkage.

With the availability of very large numbers of markers, such as microsatellite or simple-sequence repeats, genome-wide association studies (GWAS) have been made possible among nonpedigreed individuals. In contrast with QTL analyses, which are conducted in the segregating progeny of crosses between parents, GWAS are conducted among individuals of a species, which are presumed to be unrelated. After removing the potentially confounding effect of population structure, which could lead to false positives, any association between marker and a phenotypic trait could be attributed to linkage. In this way, the different genes controlling the domestication syndrome can be placed on the crop linkage map. An example of this approach is provided by association of certain genes, such as the photoreceptor gene *PHYC* and flowering time in pearl millet and changes in frequency of alleles at this locus in a 27-year period corresponding to aridity in Western Africa (Saïdou *et al.*, 2009; Vigouroux *et al.*, 2011). Another example is the identification of the *INTERMEDIUM-C* gene responsible for the 6-rowed variants in barley (*H. vulgare*) (Ramsay *et al.*, 2011).

The introduction of next-generation sequencing has made sequencing more efficient and cheaper. Hence, sequencing of multiple genotypes has also been made possible, allowing sequence comparisons on a genome-wide basis and a larger sample of genotypes. Comparisons between wild and domesticated types identify potential genome regions that have been targets of selection during the domestication process. An interesting feature of this approach is that it does not require prior knowledge or assumptions about traits under selection. In contrast with QTL and GWAS approaches, which require phenotypic variation (top-down approaches; Ross-Ibarra *et al.*, 2007), the resequencing approach is a bottom-up approach that relies on molecular population genetic arguments, such as allele frequencies differences. For example, a sharp reduction in nucleotide variation in certain areas of the genome in domesticated types compared with wild types suggests selection on phenotypes controlled by one or more genes in this region (also known as a selective sweep). Genetic drift associated with domestication would lower genetic diversity across the entire genome during and after domestication, whereas selection will be confined to those regions of the genome that contain traits under selection. The size of the region is negatively correlated with the level of recombination but positively correlated with the selection intensity. An example of this approach is the identification of a selective sweep around the waxy (wx) locus in rice. The wx locus is involved in starch metabolism in rice grains; in particular, it is responsible for the stickiness of rice grains and was selected during or after domestication in *japonica* rice (Olsen *et al.*, 2006).

In sunflower, a genome-wide study identified 36 genes showing evidence of selection during and after domestication (Chapman *et al.*, 2008). Many of the genes involved were involved in amino acid metabolism and protein catabolism (as in maize; Wright *et al.*, 2005) and were located in the same regions as previously identified QTLs for the sunflower domestication syndrome. The timing of selection could be presumably narrowed down to the initial domestication process per se or the subsequent improvement stage by distinguishing within the domesticated group between the so-called primitive (or landrace) varieties and varieties improved by selective breeding. Hufford *et al.* (2012) conducted a genome-wide resequencing in wild, landrace, and improved maize entries. Among their findings were the existence of stronger selection during the actual domestication phase than in the subsequent improvement phase. An additional observation is the existence of potential introgression from a wild relative (*Z. mays* var. *mexicana*), which is not the progenitor of maize but contributed nevertheless alleles that are potentially instrumental in adaptation to higher altitudes (van Heerwaarden *et al.*, 2011). Furthermore, several regions were identified that showed evidence of selective sweeps, representing some 1–2% of the maize gene set. Some of these genes map near QTLs that had been identified previously. As a note of caution, the separation between domestication and improvement genes may not always be clear-cut, and in some cases, such as color or shape, variants may involve arbitrary decisions as to the timing of the appearance of these variants. In addition, some domestication genes (identified as such by their absence in the wild progenitor gene pool) are not distributed across the entire domestication gene pool but characterize only a subset of the gene pool, suggesting that there is no clear dichotomy between these two classes of genes.

Concurrent with these studies, many genes controlling important domestication traits, whether they are considered domestication or improvement traits, have been isolated using map-based cloning of QTLs or a candidate gene approach, based on sequence information of genes controlling similar phenotypes in other species (Paterson *et al.*, 1995; Lenser and Theyßen, 2013). Doebley *et al.* (2006), Gross and Olsen (2010), and Olsen and Wendel (2013) presented recent overviews of genes that have been isolated. The majority of these genes are transcriptional regulators, such as the *tb1* gene in maize (conditioning the single-stem, nonbranched plant type of domesticated maize; Wang *et al.*, 1999); however, a significant proportion codes for structural genes like enzymes, such as the waxy locus (not only in rice but also in broomcorn millet and maize) and the *BADH2* gene (for rice fragrance). The types of mutations involved are diverse and include nucleotide substitutions (leading to premature stop codons or amino acid substitutions), insertions or deletions (indels), transposon insertions, or *cis*-regulatory changes (the latter outside the gene, such as is the case for the *tb1* locus controlled by an enhancer-like transposon insertion some 65 kbp upstream of the gene). In most cases, a single causative mutation can be identified. An exception to this pattern is the *PvTFL1y* gene, which is responsible for the determinate growth pattern in common bean, in which a retrotransposon insertion, synonymous substitutions, nonsynonymous substitutions, indels, a putative intron-splicing failure, and a deletion of the entire locus, all lead to loss of function, consistent with the recessive nature of the determinate phenotype (Repinski *et al.*, 2012; Kwak *et al.*, 2012). This observation suggests that the determinate trait has been selected multiple times, underscoring the importance of earliness and compact growth habit in crop cultivation.

In general, therefore, the extensive sequence data available from wild and domesticated types of major crop plants and related genetic and genomic approaches have provided a trove of information about several important features of the domestication process, including the genetic structure of the domesticated gene pool in relation to its progenitor gene pool, the effect of domestication on genetic diversity, evidence for selection, and the nature of the genes underlying domestication phenotypes.

Implications of Domestication Studies for Crop Improvement, Distributed Breeding, Redomestication, and Neodomestication

Although domestication analyses are integral part of broader studies on the origins of agriculture, results of these have important practical applications in three major areas. First, they provide essential information for conservation of genetic resources. In most, if not all, crops, improved cultivars contain less diversity than landraces (varieties selected and grown by farmers in a subsistence agriculture context) and markedly less than wild progenitors and other wild relatives because of the genetic bottleneck and selective effect that have operated during domestication and dissemination and improvement subsequent to domestication. It is hard to overestimate the importance of the diversity contained in landraces and CWR for continued improvement of crops. Yet, this diversity is also being severely threatened by a number of interconnected factors, such as habitat destruction and climate change. Both *in situ* (in farmers' fields and natural vegetation) and *ex situ* (in gene banks, botanical gardens, and other collections) approaches are being used to conserve this diversity (Gepts, 2006), but a more intensive characterization is urgently needed, at the molecular (McCouch *et al.*, 2013) and phenotypic (Furbank and Tester, 2011; Andrade-Sánchez *et al.*, 2013) levels. More basic research on plant function, especially gene interactions as well as gene–environment interactions (e.g., Mochida and Shinozaki, 2011), are required to increase the use of this genetic diversity. An additional finding – the existence of selective sweeps – has also profound impacts on breeding, because it suggests that, in addition to beneficial effects, some genes may have been introduced that have deleterious effects but are in coupling phase with the introgressed beneficial genes, a possible explanation for linkage drag. Identification of these deleterious genes and recombinants between them and beneficial genes would represent a significant progress in the introgression of genetic diversity of the exotic germplasm represented by landraces and CWR.

Domestication is not just a process that occurred at the transition from HG to agriculture. To the extent that this process involves an active and conscious selection process, it has also been operative in subsequent phases of crop evolution during the different dissemination steps to other growing regions, especially those outside the centers of origin. Current breeding efforts aiming to produce improved cultivars through selective breeding can also be construed as a step in the domestication process. During these different domestication steps, farmers have played a significant role in maintaining existing but also selecting new diversity appearing in their fields, leading to domesticated gene pools with high levels of phenotypic diversity up until the nineteenth century and beginning of the twentieth century (e.g., von Martens, 1860; Tracy, 1907; Freeman, 1912; Hedrick, 1931). Although genetic diversity in domesticated gene pools has decreased in the latter part of the tewntieth century and early twenty-first century, farmers continue to play an important role in maintaining crop genetic diversity (e.g., beans: Payró de la Cruz *et al.*, 2005; Zizumbo-Villarreal *et al.*, 2005; Worthington *et al.*, 2012; cassava: Elias *et al.*, 2001; Pujol *et al.*, 2005; pearl millet: Couturon *et al.*, 2003; Lakis *et al.*, 2011; and sorghum: Alvarez *et al.*, 2005; Barnaud *et al.*, 2008) through their knowledge of adaptation to local conditions and consumer preferences. Through their seed systems, farmers can control levels of genetic diversity, the genetic composition of their fields, and in- and outflows of diversity in their fields, including wild relatives and improved varieties.

It is this ability of farmers to recognize useful genetic variation and to assemble their own seed stock as part of the capital of their farms (Soleri *et al.*, 2002) that has led to successful efforts of participatory breeding generally involving farmers and villages in subsistence agriculture settings (e.g., maize: Smith *et al.*, 2001; barley: Ceccarelli *et al.*, 2000, 2003; common bean: Asfaw *et al.*, 2012; and agroforestry: Leakey, 2012). These participatory activities are particularly significant because they lead to a decentralized or distributed type of breeding in contrast with the current prevalent model, which is primarily centralized in public agricultural experiment stations or seed companies. Distributed breeding (by analogy with computing) may give a boost to genetic improvement by addressing local needs of farmers dictated by the needs of local adaptation and consumer preferences for individual crops. As proposed by Leakey and Asaah (2013), domestication has more than production benefits; it can have social, economic, and environmental benefits when it is applied to the entire spectrum of plants. This process includes not only continued domestication of existing crops but also incipient domestication of locally adapted, underutilized, and often perennial tree crops (for agroforestry purposes). In turn, these improved crops can play diverse roles, for example, in mitigating environmental degradation, creating new income opportunities, and promoting local employment and commerce related to food and tree products (Leakey and Asaah, 2013). This local focus of plant domestication may get a further boost in the response to climate change. The inherent uncertainty associated with climate change (e.g., Thornton *et al.*, 2009) will make it difficult to institute breeding programs with broad adaptation. Hence, to make agroecosystems more resilient, the response should be local and should combine a broad variety of responses, genetic and nongenetic, as proposed by Kiers *et al.* (2008) and Clough *et al.* (2011).

Finally, domestication is and will be playing a role in redomestication and neodomestication of plants. For example, some crops may be repurposed for an entirely different objective than the one they were first domesticated for. Maize was initially a food crop before it became an important feed crop and was also used for industrial purposes. Using maize as a feedstock for alcohol fuel production should decrease the emphasis on seed production but increase the emphasis on

vegetative matter (stems and leaves) production, essentially leading to maize varieties with reduced seed harvest index, reversing the millennia-long trend toward a higher seed harvest index. It has often been observed that domesticated plants constitute a very small fraction (<0.01%) of the total number of plant species (approximately 300 000 species; Mora *et al.*, 2011). Even if not all of plant species can be domesticated (for a variety of reasons), it seems likely that additional species can be domesticated to satisfy the needs of humanity. The experience acquired with domestication of existing crops should help one conduct deliberate and conscious neodomestication of additional plants; conversely, one does not know why so few plants have been domesticated so far. The concept of domestication potential needs to be explored further to assess which plants could be domesticated with greater ease. Further basic research in plant domestication is, therefore, needed to better understand the domestication process and the process of transition from HG to agriculture in general. These studies, although ostensibly turned toward the past, have an important practical role in the future of humanity and its well-being.

Dust Pollution from Agriculture

B Sharratt, USDA Agricultural Research Service, Pullman, WA, USA
B Auvermann, Texas A&M AgriLife Research and Extension Center, Amarillo, TX, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Dust Fine particulate matter, usually with an aerodynamic diameter of ≤10 μm.
Emission factor Amount of particulate matter emitted per unit of a specific activity.
PM2.5 Particulate matter having an aerodynamic diameter of ≤2.5 μm.
PM10 Particulate matter having an aerodynamic diameter of ≤10 μm.
TSP Total suspended particulate matter.

Dust as a Nuisance, Pollutant, and Natural Resource

Dust is often visualized as particles that are carried great distances by the wind or that reflect light and seemly shimmer when suspended in the atmosphere. Dust also casts a dull appearance or haze on otherwise bright and clean surfaces. These particles are considered by some to be a nuisance because they can mask the true appearance of a surface and require work to restore the original appearance of the surface or they can irritate our eyes or pulmonary airway. To others, dust is a valuable natural resource because it is important in the formation of raindrops and soils. The poet Robert Frost may have envisioned dust as a valued resource when he composed the following verse to the poem A Peck of Gold in 1928:

> "All the dust the wind blew high
> Appeared like gold in the sunset sky,
> But I was one of the children told
> Some of the dust was really gold."

Although this poem was written before the North American Dust Bowl of the 1930s and societal interest in natural resource conservation, farmers and land managers have long recognized dust as being the most precious of materials (gold) which comprise soils and sustain life.

Early explorers were acutely aware of the adverse effects of dust on humans. For example, Meriwether Lewis of the Lewis and Clark Expedition (Moulton, 1991) noted "… soar eyes seem to be a universal complaint among those people; I have no doubt but the fine sand of these plains and river contribute much to this disorder" while traveling along the Columbia River in the United States Pacific Northwest in 1806. Governor-in-Chief George Simpson (1826) of the Hudson Bay Company noted "This district of country is subject to very high winds which, sweeping over the sands, raise such a cloud of dust as renders it dangerous, or even impossible, to leave the house …" while traveling near Walla Walla, Washington in 1826. Little did these explorers realize that this windblown dust was the parent material from which soils formed on the Palouse, one of the most productive wheat-producing regions in the world located on the eastern edge of the Columbia Plateau along the border of modern day Idaho and Washington. Since that time, human activities undertaken to support a growing population have expanded sources from which dust is emitted into the atmosphere or exacerbated conditions that cause dust to be emitted into the atmosphere. As a result of these activities and a greater awareness of public health, nations began to adopt laws in the mid-twentieth century to protect the health and welfare of its citizens. For example, the Clean Air Act of 1971 required the United States Environmental Protection Agency (USEPA) to establish National Ambient Air Quality Standards for Particulate Matter. Air Quality Standards were established for suspended particles having a nominal diameter of ≤45 μm, but more recent legislation has set standards for regulating much smaller particles suspended in the atmosphere.

In this article, dust is defined more specifically as particles with an aerodynamic diameter ≤10 μm. This definition conforms to criteria used to describe particulate matter as a pollutant. Particulate matter having an aerodynamic diameter ≤2.5 μm (PM2.5) and ≤10 μm (PM10) are both regulated as pollutants. Many nations have created laws and established air-quality standards for regulating dust concentrations in the atmosphere. These air-quality standards were developed to protect citizens from the adverse effects of being exposed to dust. This article will, in part, review air-quality standards established by many nations throughout the world and describe techniques that are employed to measure dust concentrations in the atmosphere.

Sources that contribute to the dust load in the atmosphere can be classified as either point or nonpoint sources. Point sources emit dust into the atmosphere from a specific source or location, whereas nonpoint sources emit dust into the atmosphere from diffuse or widespread areas. Perhaps, the biggest nonpoint source of atmospheric dust is the Saharan Desert. Warren *et al.* (2007) suggested that the Bodélé Depression, located along the southern edge of the Saharan Desert, is the dustiest place on Earth. Dust storms in the Bodélé Depression occur approximately 100 days per year. Other major nonpoint sources of dust include wildfires, wood or debris burning, construction and mining sites, unpaved roads, and motor vehicles. Major point sources of atmospheric dust include foundries, paper mills, refineries, and power plants. Agricultural activities also contribute to the dust load in the atmosphere. This is, perhaps, best evidenced by long-term records which indicate a rise in atmospheric dust

concentrations after the introduction of European farming practices in the Pacific Northwest United States (Busacca *et al.*, 1998) and southeastern Australia (McGowan *et al.*, 2010).

This article focuses on agricultural sources of dust and, where possible, strategies to control dust emissions from these sources. Although the goal of developing strategies is to reduce emissions to achieve compliance with air-quality standards, these strategies must also be sustainable to ensure a viable agricultural industry.

Environmental Regulations

Many nations around the world have adopted air-quality standards to protect the health and welfare of its citizens against the adverse effects of air pollution. The World Health Organization, which has representation from 194 nations, has adopted a constitution that set guidelines on air pollutants including atmospheric dust. The guidelines established by the Organization recommend the respective daily PM2.5 and PM10 concentrations not exceed 25 and 50 $\mu g\ m^{-3}$ and the respective annual PM2.5 and PM10 concentrations not exceed 10 and 20 $\mu g\ m^{-3}$ (World Health Organization, 2005).

There is no clear and unequivocal evidence that associates adverse health effects of people to exposure to specific concentrations of particulate matter in the atmosphere. This lack of evidence is, in part, due to the variability among people in their response to exposure to particulate matter. As a result, nations have adopted guidelines or air-quality standards on the basis of availability of resources and risk assessment. Air-quality standards adopted by individual nations may, therefore, be more relaxed or more stringent than World Health Organization guidelines. The European Union, for example, has adopted a daily PM10 Air Quality Standard of 50 $\mu g\ m^{-3}$ that should not be exceeded more than 35 days per year (European Commission, 2011). The European Union has not set a daily air-quality standard for PM2.5, but has adopted an annual PM2.5 and PM10 Air Quality Standard of, respectively, 25 and 40 $\mu g\ m^{-3}$. Similarly, Australia and New Zealand have adopted a daily PM10 Standard of 50 $\mu g\ m^{-3}$, that is, respectively, not to be exceeded more than 5 and 1 day per year. The United States has adopted a daily PM2.5 Air Quality Standard of 35 $\mu g\ m^{-3}$ that should not exceed the 98th percentile averaged over 3 years and a daily PM10 Air Quality Standard of 150 $\mu g\ m^{-3}$ that should not be exceeded more than 1 day per year averaged over 3 years. Although annual concentrations of PM10 are not regulated, the United States has adopted an annual PM2.5 Air Quality Standard of 15 $\mu g\ m^{-3}$. Chile, Costa Rica, and Mexico have adopted a daily PM10 Air Quality Standard similar to the United States (not to exceed 150 $\mu g\ m^{-3}$).

New air-quality standards for particulate matter were established by China in 2012. Before this time, no air quality standard had been established for PM2.5. The new air-quality standards, which are to be implemented by residential, industrial, and rural areas across China by 2016, include a respective daily PM2.5 and PM10 concentration not to exceed 75 and 150 $\mu g\ m^{-3}$ and a respective annual PM2.5 and PM10 concentration not to exceed 35 and 70 $\mu g\ m^{-3}$.

Many communities across the world fail or have failed to comply with air-quality standards for particulate matter. Emission of particulate matter from point and nonpoint sources can contribute to the dust load and exceedance of PM2.5 and PM10 Air Quality Standards. To achieve compliance, the relative contribution of sources to overall emissions is important in devising an abatement program. For this reason, emission factors have been established to identify the relative contribution of sources to the overall dust load. Emission factors are defined as the amount of particulate matter emitted per unit of specific activity and are used to document emission inventories in Australia (http://www.npi.gov.au/), Canada (http://www.ec.gc.ca/inrp-npri/), Europe (http://www.eea.europa.eu/publications/emep-eea-emission-inventory-guidebook-2009), and the United States (http://www.epa.gov/ttn/chief/).

Techniques to Measure Dust in the Atmosphere

Dust in the atmosphere can be characterized by mass, number of particles, or size of particles using active and passive sensors. Active sensors rely on artificial aspiration to draw particles into the sensor whereas passive sensors use natural ventilation to guide particles into the sensor. Active sensors are seldom isokinetic and, thus, tend to underestimate or overestimate the mass or concentration of particles in the atmosphere. Passive sensors are dependent on wind to draw particles into the sensor and, therefore, are impractical for characterizing particles under stagnant atmospheric conditions. Although several active and passive sensors are highlighted in this section, other sensors have been developed or are commercially available to characterize atmospheric dust.

Active sensors characterize particles in the atmosphere using optical detectors, β-attenuation analyzers, and filters. The DataRAM, DustTrak, E-sampler, and Grimm Environmental Dust Monitor characterize particles using optical detectors. These detectors measure the scattering or absorption of light passing through a column of air with the amount of scattering or absorption being proportional to concentration of dust in the column of air. These sensors can be programmed to measure near real-time mass or particle characteristics, including PM10. Beta-attenuation analyzers measure the intensity of β-rays passing through dust, which is generally collected on a filter. A reduction in intensity is due to absorption of β-rays by dust on an otherwise clean filter. The Tapered Element Oscillating Microbalance (TEOM) is a common instrument used to measure near real-time PM2.5 or PM10 concentration. The TEOM (**Figure 1**) aspirates the sediment-laden air, captures the particles on a filter affixed to the end of an oscillating element, and periodically measures the oscillating frequency of that element to ascertain either PM2.5 or PM10 concentration. Both the β-attenuation analyzer and TEOM are approved devices for measuring PM10 concentration in many nations including China, the United Kingdom, and the United States. Sensors that rely on filters to extract particles from an airstream are typically classified by the volume of air moving through the sensor. Both the low-volume and high-volume sampler aspirate air at a known rate through a preweighed hydrophobic filter. The change in weight of the filter over time provides a time-integrated measure of dust in suspension. The high volume sampler (**Figure 1**) is the most

Figure 1 A Tapered Element Oscillating Microbalance (TEOM) and three High Volume samplers for measuring PM10 concentration on the leeward side of an erodible field. The inlet to the TEOM (foreground) is located above the silver enclosure (door to the enclosure is open) whereas the inlets to the High Volume samplers (behind and to the left of the TEOM) are protected by a windshield and positioned at 1, 3, and 5 m above the soil surface.

common instrument employed by regulatory agencies throughout the world for measuring PM10 concentration.

Passive sensors include the Modified Wilson and Cooke (MWAC) (Wilson and Cooke, 1980), Big Spring Number Eight (BSNE) (Fryrear, 1986), and Wedge Dust Flux Gauge (WDFG) (Hall *et al.*, 1994). These sensors manually collect airborne sediment during high wind events and are typically inspected and cleaned after each event. Another passive sensor, the Suspended Sediment Trap (SUSTRA), weighs the collected sediment for automated real-time characterization of particles (Janssen and Tetzlaff, 1991). The most widely used passive sensors include the MWAC (**Figure 2**) and the BSNE (**Figure 3**). Passive sensors vary in sampling efficiencies (percentage of sediment trapped inside the sensor to that entering the sensor) due to differences in design characteristics of the sensors. For example, the sampling efficiency of the MWAC,

Figure 3 A profile of Big Spring Number Eight sensors used to trap windblown sediment. The fins (rectangular objects to the left) maintain alignment of the sensors into the wind. The airstream enters through the rectangular opening on the windward face and exits through the wedge-shaped screen on the top of the sensor.

BSNE, WDFG, and SUSTRA sensors, respectively, vary from 90%, 40%, 22%, to 15% when trapping particles $\leq$63 μm in diameter at a wind speed of 5 m s^{-1} (Goossens and Offer, 2000). Particle size and wind speed can dramatically affect the sampling efficiency with efficiencies typically being higher when trapping larger particles or trapping particles at lower wind speeds (Goossens *et al.*, 2000; Sharratt and Feng, 2009). Sharratt and Feng (2009) observed the BSNE sensor trapped PM10 with greater efficiency at lower wind speeds with an efficiency of approximately 15% and 30% when exposed to respective wind speeds of 8 and 3 m s^{-1}.

Sources of Agricultural Dust

Dust can be generated by a multitude of activities within the agricultural industry. These activities might include traveling on unpaved roads, using an internal combustion engine, stockpiling manure, transporting feed or fiber from the field to market, feeding livestock, cleaning pens or machines, aerial spraying, and welding. This article focuses attention on two main sources of agricultural dust that pollute the atmosphere, namely, agricultural facilities and lands. Dust emitted from agricultural facilities occurs primarily from enclosures that confine livestock and store or process raw materials into feed, fiber, food, and fuel. These facilities are regulated as point sources because activities that generate dust are confined to enclosures or buildings often occupied by workers. Dust emitted from agricultural lands result primarily from natural events (e.g., high wind event) and farming operations (e.g., harvesting crops).

Agricultural Facilities

Agricultural facilities, or primarily those enclosures that confine livestock and store or process raw materials into feed, fiber, food, and fuel, can contribute to the dust load in the atmosphere. These facilities generate dust from grinding, shearing, and pulverizing raw products; dander, hair, or feather shedding from animals; or vegetative particles from crop processing, storage, and transfer. Dust emitted from these facilities can be controlled through management practices that involve filtration, design, and husbandry.

The primary risks associated with dust generated by agricultural facilities include explosions, respiratory impairment of humans or animals, nuisance (including associated odors) to neighbors, and reduced visibility (together with its associated traffic hazards). Explosions require confined spaces, threshold concentrations of entrained, flammable dusts, and an ignition source. Therefore, explosions are of concern in grain elevators, feed mills, and similar structures and facilities. Respiratory impairment of livestock and poultry in confined facilities may result in economically significant reductions in productivity or increases in maintenance costs. Exposure to dust in these facilities has more wide-ranging effects on humans, from reduced occupational productivity to impaired health. Agricultural dust as a nuisance can cause interferences in the use or enjoyment of property by neighbors whereas reduced visibilities caused by dust can be a safety hazard and detract from the enjoyment of particularly scenic areas.

Our focus will be on livestock facilities and grain storage and processing facilities that are major sources of agricultural dust.

Livestock facilities

The worldwide production of animal protein and its coproducts involve a nearly infinite spectrum of management systems. At one extreme, animals are free to roam across expansive and largely nonconfined areas. For example, cattle, sheep, and goats may be free to move within a rangeland or pasture, whereas swine and poultry may be free to roam an entire building and adjacent outdoor areas unconstrained by individual cages or pens. In these nonconfined facilities, animal excreta may be reincorporated into the landscape by natural processes or may be collected and stored for fuel or fertilizer. Dust generated from these nonconfined or open-lot facilities may originate from both animal activity as well as natural processes (erosion of the native landscape).

At the other extreme, animals live in confined or concentrated facilities. Animals in these facilities are stocked more densely in space and, in the case of poultry or veal calves, raised in cages or small hutches. Confined beef operations may be either sheltered (under roof) or nonsheltered (open lot without roof) feedyards. Feedyards may have paved or earthen surfaces and be stocked at densities such that no vegetation can be maintained on the surface. Dairy operations may use open-lot facilities similar to beef feedyards, full confinement facilities like poultry buildings, or some intermediate form such as a free-stall barn with both sheltered and nonsheltered areas accessible to the herd. Swine are generally confined within roofed facilities, with animals being segregated according to developmental stage. In confined facilities, animal excrement is periodically collected to avoid accumulation on the pen surface, which would otherwise impose stress on the animals or the broader environment. Dust from confined facilities can typically be distinguished from dust originating from the broader landscape. In the case of open-lot facilities, dust emissions are strongly modulated by weather, especially precipitation and wind speed. In contrast, dust emissions from under-roof facilities tend to be modulated more indirectly by air temperature and humidity as those variables affect mechanical ventilation rates. Some roofed facilities may be passively or naturally ventilated (instead of mechanically ventilated), in which case, dust emissions are relatively unaffected by precipitation but result primarily from the natural ventilation provided by the wind.

Our focus of discussion will be on dust emitted from confined livestock facilities.

Beef feedyards

Beef cattle are increasingly fed in confinement worldwide to capture economies of scale, increase the rate at which retail beef can be brought to market, and access markets for higher-grade beef cuts as compared with animals grazing pasture or rangeland. The United States is the leading producer of cattle for slaughter, but Australia, Canada, Argentina, Brazil, and Mexico also have significant cattle-feeding industries. Developing countries in Asia, Africa, and South America are witnessing rapid growth in the beef sector as long-term disposable income rises. Although it is possible to feed cattle in confinement in temperate and high rainfall areas, feeding systems in those areas tend to be under roof to reduce the amount of rainfall-driven wastewater that must be managed, controlled, and disposed. As a result, open-lot cattle feeding facilities tend to be more prominent in semiarid to arid climates such as the Great Plains and Southwest regions of the United States, the Prairie Provinces in Canada, and areas of Australia west of the Great Dividing Range in Queensland, New South Wales, and Victoria.

The primary prerequisite for the development of a growing cattle sector is the availability of feed grains either from local farming or imported by rail, ship, or truck. Feed grains are the primary component in fed-cattle diets. In some regions, depending on grain markets and the scale of food-processing or biofuel-processing industries nearby, the concentrate (or energy and protein fraction) in fed-cattle diets may be provided by byproducts such as processed root vegetables (e.g., potatoes and beets) or spent grains (e.g., distillers grains and sweet bran). Dust emitted from cattle feedyards is derived primarily from manure excreted by the animals, therefore the type of feed provided to confined-beef cattle is thought to influence emission rates, airborne concentrations, and particle-size characteristics of dust.

Although the cattle are in confinement, excreted manure is deposited on the pen surface and the feed apron (which may be earthen or paved). As the manure dries and is subjected to the animals' hoof action, it becomes part of the pen surface either as a well-compacted manure–soil matrix or as a noncompacted layer of material dominated by manure solids. Under dry conditions, any mechanical disturbance of the noncompacted manure layer – whether by wind scouring, animal hoof action, or operation of heavy machinery, will

generate dust particles and entrain them in the air. This dust, known as fugitive dust or dust emitted from a diffuse or nonpoint source, consists primarily of dried manure particles but will also include soil and waste feed particles, animal dander, exhaust from light vehicles and heavy machinery, dust from unpaved roads, and hair.

Fugitive dust emitted from a feedyard surface tends to be dominated by relatively coarse particles. The median aerodynamic diameter of fugitive dust from feedyards is in the range of 15–25 μm. Sweeten *et al.* (1988) reported that the ratio of PM10 to total suspended particulate (TSP) in fugitive feedyard dust, as measured by high volume samplers, is in the range of 0.19–0.40. Less is known about the relative abundance of fine particles (PM2.5) in feedyard dust, but recent measurements suggest that the PM2.5/TSP ratio is on the order of 0.05. Rainfall events reduce coarse-particle emissions to a greater extent than fine-particle emissions such that both the PM10/TSP and PM2.5/TSP ratios increase temporarily following precipitation but return to original levels within days thereafter.

Fugitive dust emissions from cattle feedyards are usually expressed as emission fluxes (mass per unit of pen area per unit time) or emission factors (mass per animal unit per unit time). These quantities are difficult to measure directly and are usually estimated by measuring dust concentrations both upwind and downwind of the source area. The measured dust concentrations are then input to a dispersion model to infer the emission flux that would have been required to generate the difference in measured concentrations. This indirect approach yields estimates of emission fluxes and emission factors that vary over an order of magnitude as shown in **Table 1**. The high uncertainty in values in **Table 1** may be expected given the differences in climate, feedyard management practices, feed composition, aerosol monitor performance, and dispersion-modeling algorithms across all studies.

Concentrations of fugitive dust in the air downwind of beef feedyards vary diurnally and seasonally depending on emission flux, topography, atmospheric stability, particle-size distribution, and the distance downwind from the source. Because these emissions occur at ground level, increasing atmospheric stability – associated with nighttime, dense daytime cloud cover, or atmospheric inversions – tends to favor higher ground-level concentrations. Even a short-term inversion may have a dramatic influence on ground-level PM concentrations, especially when the inversion coincides with periods of increased animal activity and depleted surface moisture. Under those conditions, which are quite commonly observed near sunset in semiarid and arid climates, short-term (5 min to 1 h) concentrations of fugitive dust may increase 10–15 times higher than the 24-hour average concentration (**Figure 4**). Although the absolute values of those evening peak concentrations vary up to 2 orders of magnitude from day to day, the diurnal pattern (especially in the summer) is remarkably consistent.

To the extent that wind scouring is responsible for emissions from pen surfaces, wind speed, pen-surface moisture content, and stocking density will all be important factors in determining emission fluxes and predicting downwind concentrations. The mechanisms involved in these emissions will be closely analogous to those at play in wind erosion. To date, however, wind-driven emissions of dust from cattle feedyards remain a relatively unexplored research domain.

Dairy cattle

Half of the world's dairy production occurs in the European Union, India, and the United States. Dairy operations employ either low-density pasture systems or high-density feeding systems, or a hybrid of the two, depending principally on climate. Fugitive dust from dairy production is associated primarily with high-density systems in which the animals are housed on nonvegetated or minimally vegetated open lots or in free-stall barns with outdoor exercise areas. Superficially, open lots and exercise areas on dairies resemble cattle feedyards, in that pen surfaces begin as exposed mineral soil and evolve into soil–manure mixtures that are partially compacted in place by animal activity. These surfaces are susceptible to dust emissions as noncompacted manure dries and is aerosolized by hoof action, wind scouring, or machinery operations. Dust emission processes from confinement dairies, therefore, are fundamentally similar to those of beef feedyards. Factors that control emissions, however, can differ between beef and dairy operations. First, beef animals tend to be younger, smaller, and more active than lactating cows. This leads to differences in behavior and associated hoof action and moisture-excretion rates. Second, dairy pens are temporarily emptied once or twice daily as lactating cows are moved to the

[a]Emission fluxes in this table are computed from the published emission factors on the basis of a nominal animal spacing of 14 m^2 per head. PM2.5 and PM10 are assumed to be 5% and 25% of TSP, respectively.

[b]When primary data sources for these columns were provided on an animal unit basis, we have converted them to a per-head basis by assuming a nominal mean live weight of 454 kg per head.

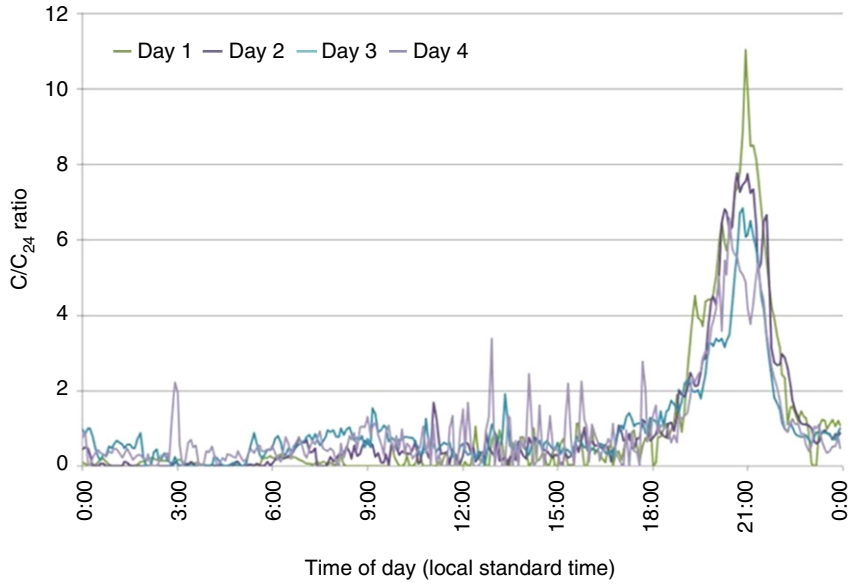

Figure 4 Typical daily variation of summertime mass concentrations (5-min averages) of fugitive PM10 downwind of a cattle feedyard in the south-central United States, normalized to the 24-h average PM10 concentration.

milking facility. Pens may then be groomed in the absence of livestock. In contrast, feedyard pens are emptied only when the cattle are being reimplanted or shipped to slaughter. Machinery operations for pen-surface maintenance on a beef feedyard must occur either when the animals are in the pen or after the cattle are shipped and the pen is empty. Third, harrowing the pen surface several times a week is commonplace in open-lot dairies. The primary reason for harrowing the pen surface in dairies is to maintain animal comfort, health, and milk production by giving the cows a softer surface on which to rest. Harrowing is not a common practice in beef feedyards except where needed to distribute bedding materials evenly across the surface. Fourth, the spatial density at which pens are stocked with animals differs widely between beef feedyards and open-lot dairies. Depending on climate, breed, topography, surface hydrology, and other factors, the average pen area allocated to a single dairy animal may be 1.5–3 times that allocated to a single beef animal. This difference in space allocation affects: the pen surface's susceptibility to wind scouring; flux of excreted and evaporated moisture; the nature and intensity of social interactions between animals; and the distribution, compaction, and rate of accumulation of manure solids. These characteristics influence dust emissions.

In addition to the differences associated with pen surfaces, patterns of truck traffic differ markedly on dairies as compared with feedyards. Depending on the size of the milk-storage tank at a dairy and the size and productivity of the dairy's milking herd, milk tankers may drive in and out 5 to 10 times per day at relatively consistent intervals. This results in periodic emissions of road dust. By contrast, comparable heavy traffic on beef feedyards involves fewer trucks and more episodic ingress and egress.

Dust concentrations downwind of open-lot dairies follow similar daily patterns to those of beef feedyards (Figure 5). As with feedyards, a pronounced evening peak in ground-level PM10 concentrations appears to be associated with temporary, regional inversions that begin shortly before sundown and persist for 4–6 hours. Notably, the ratio of the peak concentration to the 24-hour average concentration appears to be consistently lower downwind of an open-lot dairy than downwind of a cattle feedyard. This observation presumably reflects the combined effect of the major differences, outlined above, between the two types of livestock systems.

As with beef feedyards, estimates of PM2.5 and PM10 emission rates and fluxes from dairy operations vary widely (Table 2). Published research on fugitive dust emissions from open-lot dairies is much scarcer than that from beef feedyards; therefore, the uncertainties in emission estimates in Table 2 are at least as great as for beef feedyards.

Sheep and goats

Small ruminants, predominantly sheep and goats, were among the first livestock to be domesticated for food and fiber. The primary agricultural products of these animals are milk and milk products, meat, wool, mohair, and cashmere. Sheep and goats, because they are ruminants and highly adaptable, are also raised to control invasive plants.

Domesticated sheep are primarily raised in China, Australia, India, Iran, Sudan, New Zealand, and the United Kingdom. The United States is responsible for less than 1% of the world's sheep production, with the top five sheep-producing states (Texas, California, Wyoming, Colorado, and South Dakota) being semiarid and coinciding partly with North America's cattle-feeding regions. World goat production is centered in Asia and Africa with more than half the production coming from China and India. India, Bangladesh, and the Sudan dominate world production of goat milk. Goat meat production is centered in China and India, with all other nations together contributing approximately 51%. Mohair production is now centered in South Africa, with Turkey, Australia, and New Zealand having important mohair industries.

Countess Environmental (2006)[c]	Synthesis of data	0.1	0.8	1.7	0.3	3	6.5

[a]Emission fluxes in this table were computed from published emission factors on the basis of a nominal animal spacing of 37.2 m^2 per head. PM2.5 and PM10 are assumed to be 5% and 25% of TSP, respectively, except where noted.

[b]When primary data sources for these columns were provided on an animal unit basis, we have converted to a per-head basis on the assumption of standard Holstein cows having a nominal live weight of 636 kg per head.

[c]PM2.5 and PM10 emission factors were determined on the basis of the California Air Resources Board guidance that assumes PM10 and PM2.5 are 48% and 5.3% of TSP, respectively.

Most of the sheep and goats raised around the world are pastured, with sheep preferring grasslands and goats being raised in more woody or brushy rangelands. Animals raised for milk may be confined near the milking parlor during the winter months. Sheep and goats raised for meat or fiber typically live on pasture or range, but meat animals may be finished on grain-based diets to achieve desirable meat qualities. Nonvegetated sheep and goat feedlots are common in the United States and Australia and have many similarities to cattle feedyards and, to a lesser extent, open-lot dairies. As with the beef and open-lot dairy operations, dust emissions and downwind concentrations from sheep and goat feedlots are driven by regional climate, short-term weather phenomena, feeding and pen-surface management, and patterns of animal activity. However, researchers have not examined emission rates of fugitive dust from sheep and goat feedlots. Fully confined (i.e., in buildings or under roof) sheep and goat production does have a substantial presence in Europe, and limited research there has provided some estimates of emission rates and concentrations of dust associated with total-confinement facilities. Aarnink *et al.* (2012) reported annual emissions of TSP at 69 g per head, PM10 at 22 g per head, and PM2.5 at 1 g per head from goat houses in the Netherlands. Dust emissions were largely attributed to the straw used for bedding inside the houses and, to a lesser extent, dry fecal material resuspended in air by animal activity. Papanastasiou *et al.* (2011) reported that PM10 and PM2.5 concentrations inside sheep houses in Greece varied inversely with ventilation rate, but they measured neither outdoor concentrations nor emission rates through the ventilation system.

Swine and poultry

Swine, poultry meat, and eggs are produced at respective annual rates of 110, 87, and 68 million metric tons worldwide, as compared with beef (62 million tons), mutton/lamb (14 million tons), and milk (671 million tons) (UNFAO, 2009). As nonruminants, pigs and poultry cannot be raised on grass or

other forages. Therefore, pork, poultry meat, and eggs are produced predominantly in a wide range of confinement systems. Swine and poultry facilities may be fully or quasi-confined, roofed or open-lot, actively or passively ventilated, and on earthen or paved surfaces. Quasi-confined facilities allow animals to move liberally around a relatively large and partial-outdoor environment, but are fed in specified locations. Examples of quasi-confined facilities include free-range areas for poultry and hoop barns for swine. By contrast, fully confined facilities are essentially designed to optimize the animals' stocking density and to control their environment for economic productivity. Although there is some trend toward quasi-confined facilities for the sake of animal-welfare considerations, the majority of swine, poultry meat, and eggs is produced under roof with controlled or semicontrolled indoor environments. As a result, most of the dust emitted from swine or poultry houses originates as an indoor air pollutant that poses health and productivity risks to both the animals and the workers. Where natural wind currents are insufficient to maintain acceptable indoor air quality, forced ventilation, and attentive dust-management practices in swine (Pedersen *et al.*, 2000) and poultry houses are essential. Among all of the world's major livestock-production systems, swine and poultry houses have been the most extensively studied with respect to dust concentrations, characteristics, and emissions.

Swine

China accounts for nearly one-half, whereas the European Union accounts for 20% and the United States and Brazil together account for 10% of the world's swine production (USDA, 2012). Swine production generally involves the use of confined facilities with houses having paved or earthen floors, natural or artificial lighting, and passive or forced ventilation. Moreover, different growth stages of the animals may be raised in different housing types to ensure that animals in the growth stages most vulnerable to health impairment or productivity loss (sows, baby pigs, and breeding boars) are subjected to the least environmental stress. As a result, the sources, mechanisms, and characteristics of dust produced in swine houses may be meaningfully stratified by animal growth stage. For example, one recent study found that dust from a growing-finishing house, in which slaughter pigs were fed on a concrete, partially slatted floor, was composed primarily of feed, feces, and skin particles. In contrast, dust was largely composed of straw fragments when finishing houses used straw for bedding material (Aarnink *et al.*, 2004). Reflecting the diversity in swine-production systems, Haeussermann *et al.* (2008) developed a mathematical model to predict PM10 emissions from swine facilities that accounted for variations in stocking rate, animal liveweight, animal growth stage, and characteristics of the housing system.

The rate at which dust is emitted from swine houses is governed by the indoor dust concentration and the ventilation rate, both of which vary strongly with time. Estimating emissions from houses with forced-air ventilation systems involves continuously measuring the flow rate of air through the exhaust fans and synchronized monitoring of indoor dust concentrations at the fan intake (Hinz and Linke, 1998a). Emissions from passively ventilated houses are more difficult to measure and are characterized by greater uncertainty, as airflow patterns (directions and flow rates) are highly variable. In a study at a swine finishing house, Hinz and Linke (1998b) found total dust concentrations as high as 5000 $\mu g\ m^{-3}$ during the daytime when animal activity was high and as high as 2000 $\mu g\ m^{-3}$ during the nighttime hours. Emission rates of inhalable dust (nominally PM10) from swine houses in northern Europe ranged from 121 to 1364 $mg\ h^{-1}$ per 500 kg of animal liveweight in the house, suggesting that dust-emission rates scale approximately with each facility's animal capacity (Takai *et al.*, 1998).

Poultry

Eggs, broiler chickens, turkeys, and other poultry products are important sources of animal protein throughout the world. The United States leads global production of broiler meat (20%), with China, Brazil, and the European Union together producing another 40%. The United States also produces more than half of the world's turkey meat, followed by the European Union, Brazil, and Canada (Pedersen *et al.*, 2000). Of the approximately one trillion eggs produced globally per year, China produces approximately half and the United States another 10%. India, Japan, European Union, Mexico, and Russia round out the top seven egg-producing regions.

Broiler and turkey houses are typically designed to raise the birds on bedding materials (e.g., sawdust, wood shavings, and crop residues) that optimize meat quality and growth rates while absorbing excreta. Dust from poultry raised for meat is composed of feather fragments, crystals from dried urine, feed and feces particles, bedding fragments, and microorganisms (Aarnink *et al.*, 2004). Layer houses, by contrast, seldom have bedding; excreta are collected and removed frequently or even continuously. Animals in layer houses are raised in cages, or stacks of cages, that facilitate egg removal. As a result, dust from broiler and turkey houses differs from that of layer houses, both in composition and emission rates (Seedorf *et al.*, 1998; Takai *et al.*, 1998).

As with swine facilities, dust emissions from broiler houses tend to scale with the total liveweight housed in a single building (Hinz and Linke, 1998b). In northern Europe, researchers (Takai *et al.*, 1998) found that inhalable dust (nominally PM10) concentrations in caged-layer and broiler houses ranged from 750 to 1640 and 3830 to 10 360 $\mu g\ m^{-3}$, respectively, with emission rates ranging from 398 to 872 and 1856 to 6218 $mg\ h^{-1}$, respectively, per 500 kg of animal liveweight in the houses.

Processing and storage facilities

Dust generated in facilities that process or store raw materials for manufacturing feed, food, fiber, or fuel is of particular concern to the occupational safety and welfare of workers within these facilities. Explosions and fires at grain-storage facilities are not uncommon and can result in death of occupants; such an explosion killed six workers at a facility in Atchison, Kansas in 2011. The health of occupants can also be impaired by inhaling dust within or near these facilities. Dust generated at grain-processing facilities can be even more hazardous than storage facilities because processing involves grinding grain into fine particles. Agricultural processing and storage facilities that are major sources of dust include cotton gins, grain elevators, and feed mills.

Cotton gins

Cotton is a natural fiber derived from the fruit, or boll, of the woody plant. Cotton requires a long growing season with abundant sunshine; thus, it is grown throughout the desert, temperate, and tropical climates of the world. Most of the cotton produced worldwide comes from Asia (i.e., China, India, Pakistan), Brazil, Australia, Turkey, and the United States. In the United States, major cotton-growing states include California, Georgia, Mississippi, and Texas. Together, China and India are responsible for more than half of the world's cotton production.

The mature cotton boll consists of three main parts, namely the seed, lint, and burr. The seed is high in protein and oil and is embedded within and attached to the lint; the lint consists of fibers used to manufacture fabrics. Modern cotton harvesting is highly automated and is accomplished with either a cotton picker or cotton stripper. Cotton pickers are designed to mimic the selective action of manual harvesting and may pass through a field more than once. Cotton strippers move more quickly through the field and strip nearly all of the bolls from the plant leaving behind the main stalk and larger stems. The raw products obtained from these two harvesters differ primarily in terms of the relative amounts of mature versus immature lint and the amount of nonlint material in the harvested bulk.

Cotton ginning is essentially a two-stage mechanical process of removing gin trash (stems, burrs, soil, and other debris) from cotton bolls and separating the cotton fibers from the seed. The modern cotton gin originated in the late eighteenth century but has become a highly sophisticated, multistage, high-throughput operation that yields compressed lint bales weighing 200–225 kg. Cotton gins now consist of many specialized, mechanical processes (**Figure 6**). The conveyors in a cotton gin are pneumatic, using air flow at high speed to move the materials from point to point. Along the way, debris, lint, and seeds must be removed from the various air streams with the conveying air ultimately exhausted to the outside.

Dust emissions from cotton gins originate from the exhaust of conveying systems within the gin enclosure. The dust consists of soil particles, insect fragments, and fragments of lint, leaves, stems, and other plant parts. Each of the specialized, mechanical processes within a gin produces a characteristic type of dust. Moreover, the manner in which the cotton is harvest (i.e., picker vs. stripper) strongly influences the load on each stage of the ginning process. Stripper-harvested cotton may generate 6–7 times as much trash during the ginning process as picker-harvested cotton (USEPA, 1995).

As with most agricultural dusts, cotton gin dust is composed of both organic (plant-derived) and mineral (soil derived) particles. Most of the dust generated by cotton ginning, therefore, is relatively coarse with aerodynamic diameters exceeding 10 μm. The ratio of PM10 to TSP varies slightly between processes, but is typically between 0.25 and 0.5. In addition to the parent materials, dust associated with cotton-gin exhaust may also contain traces of chemical residues, including pesticides and harvest aids (defoliants).

As implied by **Figure 6**, estimates of the total dust emissions from cotton gins are assembled from individual process emissions. As shown in **Table 3**, emissions are typically calculated from an emission factor for each process (mass of particles per bale of cotton produced) multiplied by the gin's throughput (bales per unit of time). Modern, high-capacity gins can process 1500 bales per day.

Concentrations of dust at ground level downwind of cotton gins depend on the efficiency of the control systems (cyclones and screens); the elevation of the exhaust points; the flow velocities, orientation, and temperatures of the exhaust streams; and atmospheric conditions. Every cotton gin is unique, but ground-level concentrations of PM10 and TSP have been measured over the past several decades. Recently, Hughs *et al.* (2008) measured respective daily PM2.5 and PM10 concentrations of 0.02–0.92 and 5–40 $\mu g\, m^{-3}$ downwind of a gin in the southwestern United States.

Grain elevators and feed mills

Grain-storage and grain-processing facilities are found across a wide range of sizes, configurations, and capacities throughout the world. For example, individual farmers may have on-site bunkers and silos for grain storage. Local farmers' cooperatives typically have one or more storage elevators, sometimes known as country elevators, to facilitate grain marketing for their members. Animal-feeding operations may also use bunkers and silos to store and mills to process grains and other components into animal feed. Flour mills, bread factories, breweries, and other grain-processing industries may maintain on-site storage of grains to ensure adequate production capacity. Regional transfer facilities in larger towns and cities will aggregate grain from surrounding country elevators into numerous, large elevators for long-distance transport by rail or tractor-trailer. Terminals and processing facilities along major waterways or harbors will have sizeable elevators and mills to store and process a wide range of grains for import/export markets. At all scales, however, the dust associated with loading, unloading, transferring, storing, and processing grain has significant implications for human safety, human health, and environmental air quality.

Grain dust, which is rich in organic carbon, is highly flammable and can detonate or deflagrate, with catastrophic results in fatalities, injuries, and loss of property. The risk of grain-dust explosions is present when the suspended dust concentration exceeds the minimum explosive concentration (MEC), dusty air is confined within an enclosed space, adequate oxygen is available to support combustion, and an ignition source (e.g., static electricity, electrical shorts or loose connections, unsealed motors, pilot lights, failing bearings between metal parts, and cigarettes) is present (Jones, 2011). Particles of grain dust are intrinsically flammable, but their explosive risk increases as particle size decreases. The MEC of grain dusts may be as low as 45–50 $g\, m^{-3}$, with optimum explosive concentrations between 100 and 150 $g\, m^{-3}$ (Gillis, 1985).

Occupational health is at risk when grain-storage or grain-processing workers do not wear adequate respiratory protection. Grain dusts may include soil particles, fragments of plant tissues and grains, insect fragments, mold spores, fungi, bacteria, viruses, and other biological aerosols. Even when biological aerosols are noninfectious, they may contain nonviable or dead organisms whose cellular components (e.g., endotoxins, lipopolysaccharides, and peptidoglycans) may be toxic to humans, with either chronic or acute health effects

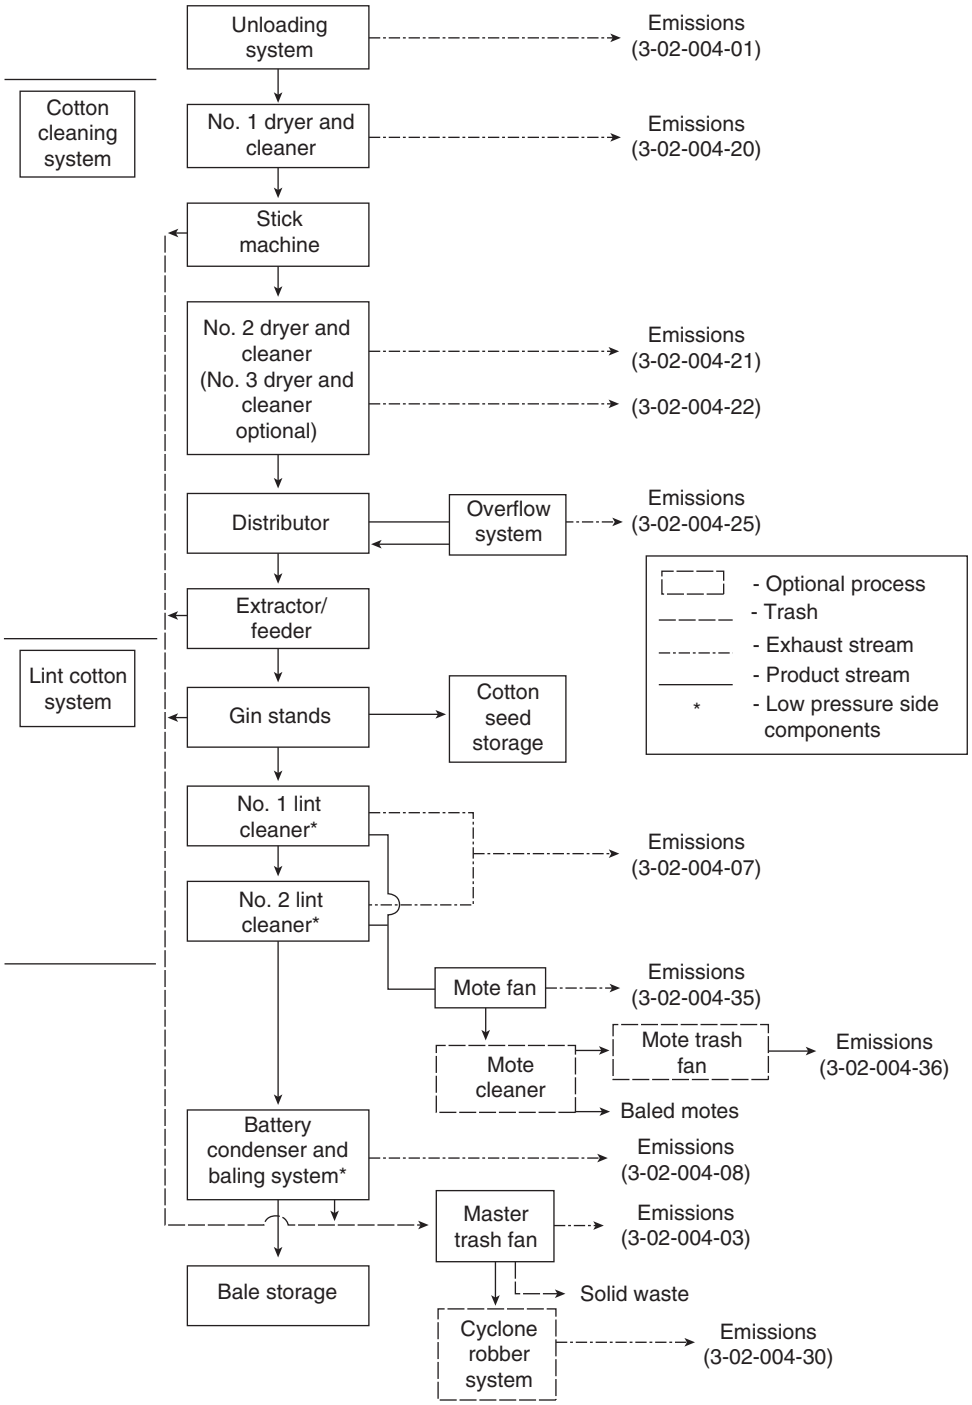

Figure 6 Schematic of a modern cotton gin showing the numerous discrete processes that generate dust emissions (USEPA, 1995). Numbers in parentheses are Source Classification Codes used by the USEPA to categorize operations that emit particulate matter.

(Schwartz *et al.*, 1995). Environmental air quality may also be a concern for neighboring residences and communities, especially for susceptible persons including the young, elderly, asthmatics, or those with weak or compromised immune function. In general, grain dust from elevators and feed mills is a class of air pollutants subject to governmental regulatory standards.

Emission rates from elevators and mills are generally computed using emission factors or process-weight tables and, similar to cotton gins, each discrete process within an elevator or mill will have its own emission factor (**Figure 7**). For example, the emission factor for grain cleaning in elevators or grain crushing in feed mills is at least twice that of receiving grain at either facility (**Table 4**). In addition, each

Table 3 Emission factors for modern cotton gins with high-efficiency cyclone controls on the exhaust streams (USEPA, 1995)

Source	*TSP (kg bale^{-1})*	*PM10 (kg bale^{-1})*	*PM10/TSP ratio*
Unloading fan	0.132	0.055	0.41
#1 Dryer/cleaner	0.164	0.005	0.03
#2 Dryer/cleaner	0.109	0.042	0.39
#3 Dryer/cleaner	0.043	0.015	0.35
Overflow fan	0.032	0.012	0.37
Lint cleaners:			
• with high-efficiency cyclones	0.264	0.109	0.41
• with screen drums or cages	0.500	–	–
Cyclone robber	0.082	0.024	0.29
Mote fan	0.127	0.059	0.46
Mote trash fan	0.035	0.010	0.27
Battery condenser:			
• with high-efficiency cyclones	0.018	0.006	0.36
• with screen drums or cages	0.077	–	–
Master trash fan	0.245	0.034	0.14
Grand total	1.828	0.370	0.30

type of grain has its own intrinsic dustiness, which may vary with moisture content, harvest method, or other management factors (USEPA, 2003). In principle, then, there could be a unique emission factor for each permutation of grain type, grain condition, harvest method, and elevator or mill process.

Agricultural Lands

Agricultural lands, primarily in the arid and semiarid regions of the world, contribute to the dust load in the atmosphere. The lack of precipitation in these regions impairs crop production and generally results in dry and poorly structured soils, both of which affect dust emissions from agricultural lands. Dust is emitted into the atmosphere from agricultural lands as a result of natural events and farming operations. Although natural events cannot be controlled or regulated, management practices or farming operations imposed on these lands can dramatically influence dust emissions.

Natural events

High winds, volcanic eruptions, and wildfires are natural events that can affect atmospheric PM10 concentrations. High-wind events are of particular relevance to agriculture. Dust emitted into the atmosphere as a result of high winds eroding agricultural lands (**Figure 8**) constitutes 10% of the atmospheric dust load worldwide (Tegen *et al.*, 2004). Windblown dust has contributed to exceedance of national PM10 air-quality standards in China, Europe, and the United States (Liu *et al.*, 2011; Escudero *et al.*, 2007; Sharratt and Lauer, 2006). Long-range transport of PM10 from eroding agricultural land has also contributed to exceedance of PM10 air-quality standards. For example, transport from agricultural lands in the Ukraine have resulted in exceedance of the European Union air quality standard for PM10 (daily concentration not to exceed 50 μg m^{-3}) in Slovakia, the Czech Republic, Poland, and Germany (Birmili *et al.*, 2008) whereas transport from agricultural lands in Africa has contributed to exceedance of the European Union PM10 air-quality standard in Spain (Escudero *et al.*, 2007). Although intercontinental transport of dust has not contributed to the exceedance of PM10 Standards in the United States, erosion of agricultural lands in China (Wang *et al.*, 2004) has contributed to a rise in PM10 concentrations in the Pacific Northwest of greater than 100 μg m^{-3} (Husar *et al.*, 2001). In the United States, windblown dust generated from agricultural lands has contributed to exceedance of the PM10 Air Quality Standard in Arizona (Fields *et al.*, 2001), California (Chow and Watson, 2001), and Washington (Sharratt and Lauer, 2006).

Very few studies have examined the emission of PM2.5 or PM10 from agricultural lands during high-wind events (**Table 5**). Sharratt *et al.* (2007) measured a PM10 concentration of greater than 8500 μg m^{-3} above an eroding agricultural field during a high-wind event in eastern Washington. More recent field data collected in eastern Washington indicate that PM10 concentration and vertical flux can exceed those in **Table 5**. For example, PM10 concentration and vertical flux, respectively, exceeded 70 000 μg m^{-3} and 10 000 μg m^{-2} s^{-1} above an eroding agricultural field during a high-wind event on 3 September 2009 (**Figure 9**). The daily PM10 concentration at a 2 m height during this high-wind event was 1735 μg m^{-3}. Others have measured concentrations and fluxes of fine particles above eroding agricultural fields, but these measurements have been limited to particles either smaller or larger than 10 μm in diameter. For example, Gillette *et al.* (1972) observed a vertical flux of PM6 (particles with aerodynamic diameters ≤6 μm) of 1 μg m^{-2} s^{-1} over an eroding field before sowing wheat in Nebraska. Gillette (1977) observed a vertical flux of PM20 (particles with geometric diameters of <20 μm) of 10 to 5×10^{5} μg m^{-2} s^{-1} above eroding sands, loamy sands, sandy loams, and clays in Texas. Gomes *et al.* (2003) have reported vertical fluxes of PM20 of respectively 66 and 302 μg m^{-2} s^{-1} over eroding agricultural fields in Spain and Niger.

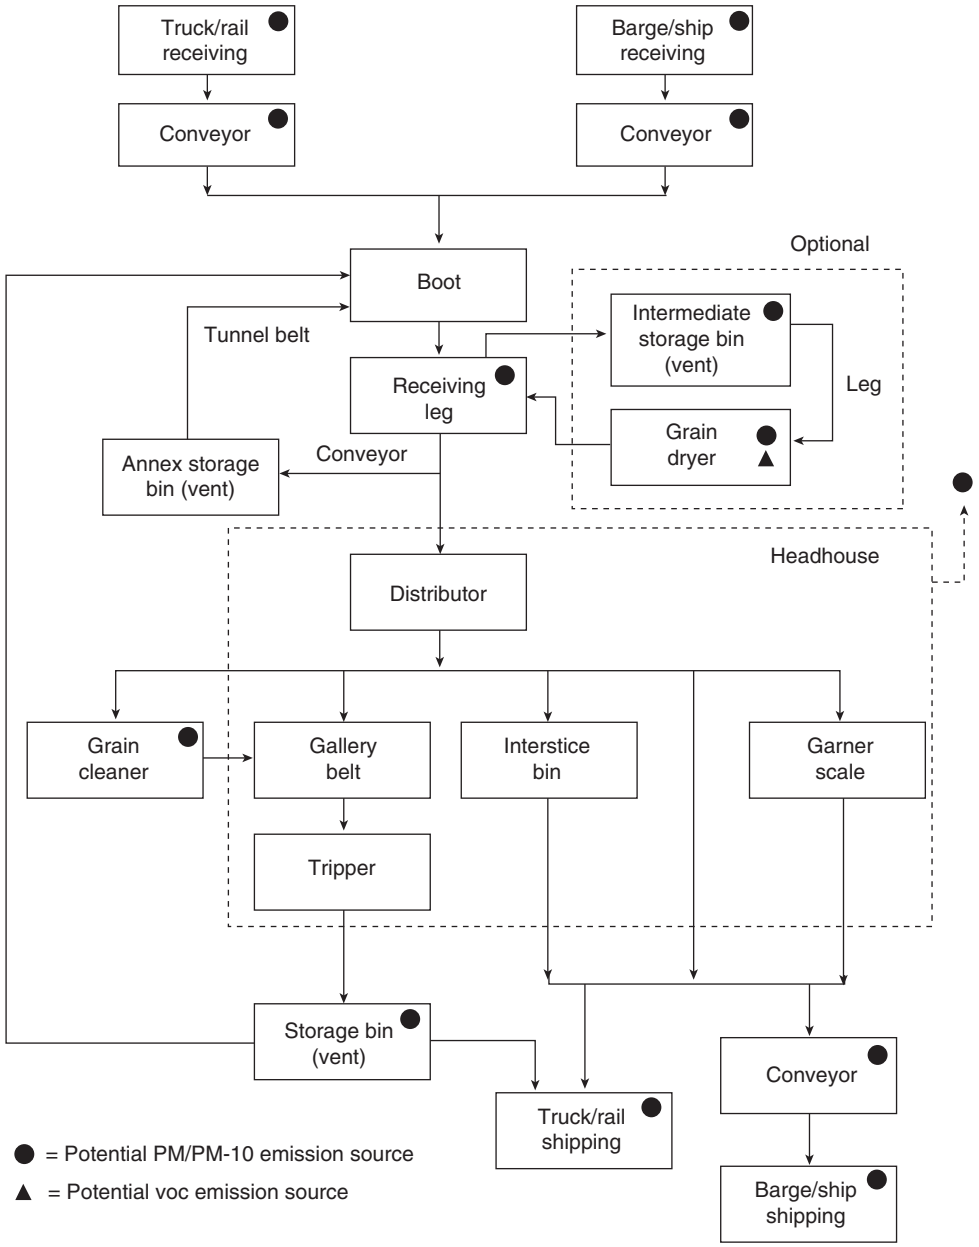

Figure 7 Schematic of emissions sources in a grain elevator (USEPA, 2003). VOC, volatile organic compound.

Table 4 Example emission factors for processes within grain elevators and feed mills in the United States (USEPA, 2003)

Process	*TSP emission factor (g mg^{-1})*	*PM10 emission factor (g mg^{-1})*	*PM10/TSP ratio*
Feed mill:			
• Grain receiving	8.5	1.25	0.15
• Hammer mill with cyclone	33.5		
• Feed shipping	1.65	0.4	0.24
Grain elevator:			
• Grain cleaning with cyclone	37.5	9.5	0.25
• Grain receiving, hopper truck	17.5	3.9	0.22
• Grain handling	12.5	3.15	0.25

Two studies have estimated PM10 emissions from agricultural lands during high winds. Saxton *et al.* (2000) estimated PM10 vertical fluxes as high as 300 000 $\mu g\ m^{-2}\ s^{-1}$ from agricultural fields during a design wind storm in some portions of the Columbia Plateau. These estimates, based on an integrated meteorological/chemical transport/PM10 emissions model, were not confirmed in the field. Xuan and Sokolik (2002) estimated an annual PM10 loss across gridded locations in northern China using an empirical model which estimates PM10 loss from surface characteristics and climate. Their analyses suggest that annual PM10 loss can approach 10 $kg\ ha^{-1}$ in agricultural regions.

Geologic material is generally composed of coarser particle matter and, thus, PM2.5 constitutes a small percentage of PM10 emitted from agricultural lands. For example, PM2.5 comprised from 4% to 7% of PM10 that was observed downwind of eroding agricultural lands in the Columbia Plateau region of the Inland Pacific Northwest (Sharratt and Lauer, 2006). Gillette and Walker (1977) measured the size distribution of particulate matter 1.5 m above eroding agricultural soils in Texas and found that PM2.5 comprised from approximately 1% to 4% of PM10.

Best management practices to reduce dust emissions from agricultural soils during high-wind events are similar to those required to control wind erosion. These practices include the use of wind barriers, ridge tillage, tillage operations that enhance surface roughness or cover with crop residue, mulching with vegetation or manure, cover crops, perennial, or multiyear crops, strip cropping, delayed tillage, and sowing when soil moisture is adequate for timely seed germination and emergence. Fields *et al.* (2001) estimated the reduction in emissions during a high-wind event in Arizona for various management practices and found that multiyear crops, residue management, and timing of tillage operations were the best strategies for reducing PM10 emission from cropland.

Figure 8 Dust rising from an isolated cultivated field during an October 2003 high-wind event near Ralston, WA, USA.

Farming operations

Tillage, harvest, seeding, fertilizing, and spraying are routine farming operations that generate dust. Dust generated by agricultural operations is typically characterized by particles with diameters larger than 2.5 μm (Capareda *et al.*, 2004) and, therefore, does not solely contribute to exceedance of the PM2.5 air-quality standard. Dust emitted into the atmosphere as a result of farming operations has contributed to the exceedance of the PM10 air-quality standards in the United States, most notably in California (Chow *et al.*, 1992; Dolislager and Motallebi, 1999). Dust generated by farming operations is the second largest source, with road dust being the largest source, in the San Joaquin Valley of California (Cassel *et al.*, 2003). Air stagnation in the Imperial Valley and San Joaquin Valley during the autumn, winter, and spring trap fine particles in the atmosphere that are emitted during tillage or harvest operations (Chow and Watson, 2001). In northern Europe, high atmospheric dust concentrations in the spring have been linked to tillage activities (Goossens, 2004).

Tillage and harvest operations typically generate a higher proportion of coarse particulate matter (particulates with a diameter 2.5–10 μm) as compared with PM2.5 (Matsumura *et al.*, 2003; Kasumba *et al.*, 2011). Particulates emitted during tillage or land preparation operations are affected by the type of implement, speed of implement, surface characteristics (e.g., roughness and residue cover), soil properties (e.g., type and moisture), and atmospheric conditions. Particulates emitted during harvest, however, tend to be unique to each crop. Some crops require only one harvest operation (e.g., direct combine), whereas the harvest of other crops, such as nut trees, require multiple operations. Each operation can contribute to the particulate load in the atmosphere. Particulates can be emitted during the cutting, swathing, raking, or combining operations of field crops or the shaking, sweeping, and pickup operations of tree crops. For example, the harvest of almonds in California involves shaking the tree to allow the

almonds to fall to the soil surface to air dry, sweeping the almonds on the soil surface into windrows, and picking up the almonds from the soil surface with a machine that separates the almonds from the soil and other debris. Each sequential operation emits one magnitude more PM10 into the atmosphere (Faulkner and Capareda, 2012). PM2.5 and PM10 emission factors for tillage and harvest operations are provided in **Table 6**. The range in emission factors for any operation is likely due to differences in atmospheric conditions (e.g., relative humidity), moisture content of soil, depth of tillage, implement speed through the field during the operation, and methodology used to measure emissions during the operation. Virtually no information is available on PM10 emission factors for seeding, fertilizing, and spraying operations. However, data of Bogman *et al.* (2007) would suggest that the PM10 emission factor for the seeding operation is similar to the plowing or disking operations whereas the PM10 emission factors for fertilizing and spraying operations are an order of magnitude less than the cultivating, disking, and plowing operations.

Exceedance of PM10 air-quality standards due to farming operations have forced local or national government organizations to adopt alternative practices that emit less particulate matter into the atmosphere. For example, exceedance of the PM10 standard in Maricopa County prompted the development of best management practices to reduce dust emissions from agricultural lands in Arizona (State of Arizona, 2008). Best management practices for field crops include using one-pass operations (e.g., apply fertilizer when cultivating or seeding), reduced or no tillage practices, tillage tools that do not invert the soil, and stripper headers rather than traditional headers on combines. Other best management practices include cultivating the soil at lower speeds or when the soil is moist, roughening the soil surface, and minimizing the chopping and spreading of residue from the combine. Best management practices for tree crops include sweeping or pickup of nuts from the soil surface when the surface is moist and using less invasive operations and modified harvest equipment.

Biomass burning

Biomass burning is used throughout the world to control diseases and pests in crops, remove crop residue that otherwise interferes with harvest or seeding operations, and as a fuel source. Biomass burning, however, can contribute to the dust load in the atmosphere. For example, burning wheat and corn residue is a major contributor to high PM2.5 concentrations in Beijing, China (Li *et al.*, 2007; Song *et al.*, 2006), whereas burning sugarcane is the main source of PM2.5 in some Brazilian cities (Lara *et al.*, 2005). Burning biomass generates a higher proportion of PM2.5 as compared with coarser particulate matter. In fact, 93% and 98% of the PM10 liberated from burning respectively wheat straw and corn stover is PM2.5 (Li *et al.*, 2007). In addition, biomass burning can release toxic compounds such as polycyclic aromatic hydrocarbons and phenols. PM2.5 and PM10 emission factors for burning agricultural residues are provided in **Table 7**. The range in emission factors for any crop is likely due to differences in atmospheric conditions (e.g., relative humidity), configuration of residue, or moisture content of residue during the burn.

A greater awareness of biomass burning being a source of atmospheric PM2.5 has prompted government organizations around the world to adopt policies that regulate burning of crop residue. In Washington, for example, agricultural burning has been reduced by half over the past decade and is currently allowed on certain days by those possessing a permit. Violation of this law has resulted in fines that exceed US$20 000. Other methods of handling crop residue are being advocated rather than burning; these include removing residue from the soil surface after harvest, incorporating residue into the soil after harvest, or using no-till seeding technologies and pesticides.

Future Perspectives

The pursuit of clean air will intensify as societies become more urbanized and interest escalates in protecting public health. Air-quality standards are being adopted and revised by many nations around the world. For example, China will fully implement new air-quality standards by 2016. In addition, the USEPA is mandated to review and revise, if appropriate, air-quality standards every 5 years. There is expectation that stricter or tighter PM2.5 and PM10 air-quality standards will be adopted as more evidence associates adverse health effects with exposure to dust. Tighter or more restrictive air-quality standards will necessitate that even greater measures be taken or better practices be implemented to control dust emissions. This will be a challenge for the agricultural industry, particularly in regions where weather affects emissions and profit margins are thin. Meeting this challenge will require the development of more cost-effective practices to control dust emissions from agricultural facilities and lands.

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is arranged as a series of articles in alphabetical order.

There are four features to help you easily find the topic you're interested in: an alphabetical contents list, cross-references to other relevant articles within each article, and a full subject index.

1 Alphabetical Contents List

The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

2 Cross-References

Most of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an entry as a See also list, serve four different functions:

i. To draw the reader's attention to related material in other entries.
ii. To indicate material that broadens and extends the scope of the article.
iii. To indicate material that covers a topic in more depth.
iv. To direct readers to other articles by the same author(s).

Example

The following list of cross-references appears at the end of the entry Critical Tracking Events Approach to Food Traceability.

> *See also*: Agribusiness Organization and Management. Food Chain: Farm to Market. Food Labeling. Food Law. Food Packaging. Food Security: Development Strategies. Food Security: Food Defense and Biosecurity. Food Security, Market Processes, and the Role of Government Policy. Food Security: Postharvest Losses. Global Food Supply Chains. Government Agricultural Policy, United States. Regulatory Conventions and Institutions that Govern Global Agricultural Trade

3 Index

The index includes page numbers for quick reference to the information you're looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.

4 Contributors

At the start of each volume there is list of the authors who contributed to that volume.

SUBJECT CLASSIFICATION

Agriculture and People

Agribusiness Organization and Management
Agricultural Cooperatives
Agricultural Ethics and Social Justice
Agricultural Finance
Agricultural Labor: Demand for Labor
Agricultural Labor: Gender Issues
Agricultural Labor: Labor Market Operation
Agricultural Labor: Supply of Labor
Agricultural Law
Agricultural Policy: A Global View
Analyses of Total Phenolics, Total Flavonoids, and Total Antioxidant Activities in Foods and Dietary Supplements
Changing Structure and Organization of US Agriculture
Climate Change, Society, and Agriculture: An Economic and Policy Perspective
Computer Modeling: Policy Analysis and Simulation
Consumer-Oriented New Product Development
Crop Insurance
Determining Functional Properties and Sources of Recently Identified Bioactive Food Components: Oligosaccharides, Glycolipids, Glycoproteins, and Peptides
Farm Management
Food Chain: Farm to Market
Food Labeling
Food Law
Food Marketing
Food Security, Market Processes, and the Role of Government Policy
Food Security: Development Strategies
Food Security: Food Defense and Biosecurity
From Foraging to Agriculture
Global Food Supply Chains
Government Agricultural Policy, United States
Human Nutrition: Malnutrition and Diet
Industrialized Farming and Its Relationship to Community Well-Being
Intellectual Property in Agriculture
International and Regional Institutions and Instruments for Agricultural Policy, Research, and Development
International Trade
Investments in and the Economic Returns to Agricultural and Food R&D Worldwide
Markets and Prices
Mathematical Models to Elaborate Plans for Adaptation of Rural Communities to Climate Change
Policy Frameworks for International Agricultural and Rural Development
Production Economics
Quantitative Methods in Agricultural Economics
Regulatory Conventions and Institutions that Govern Global Agricultural Trade
Rural Sociology
Safety of Street Food: Indonesia's Experience
Social Justice: Preservation of Cultures in Traditional Agriculture
Vitamins and Food-Derived Biofactors

Agriculture and the Environment

Agroforestry: Conservation Trees and Erosion Prevention
Agroforestry: Hydrological Impacts
Air: Confined Animal Facilities and Air Quality Issues
Air: Greenhouse Gases from Agriculture
Biodiversity and Ecosystem Services in Agroecosystems
Biodiversity: Conserving Biodiversity in Agroecosystems
Climate Change: Agricultural Mitigation
Computer Modeling: Applications to Environment and Food Security
Crop Pollination
Dust Pollution from Agriculture
Ecoagriculture: Integrated Landscape Management for People, Food, and Nature
Economics of Natural Resources and Environment in Agriculture
Energy and Greenhouse Gases Footprint of Food Processing
Land Use: Catchment Management
Land Use, Land Cover, and Food-Energy-Environment Trade-Off: Key Issues and Insights for Millennium Development Goals
Land Use: Management for Biodiversity and Conservation
Land Use: Restoration and Rehabilitation
Linkages of the Agricultural Sector: Models and Precautions
Market-Based Incentives for the Conservation of Ecosystem Services in Agricultural Landscapes: Examples from Coffee Cultivation in Latin America
Natural Capital, Ecological Infrastructure, and Ecosystem Services in Agroecosystems

Soil: Carbon Sequestration in Agricultural Systems
Soil: Conservation Practices
Soil Greenhouse Gas Emissions and Their Mitigation
Soil: Nutrient Cycling
Virtual Water and Water Footprint of Food Production and Processing
Water: Advanced Irrigation Technologies
Water Use: Recycling and Desalination for Agriculture
Water: Water Quality and Challenges from Agriculture
Weather Forecasting Applications in Agriculture
World Water Supply and Use: Challenges for the Future

Agriculture Products

Advances in Pesticide Risk Reduction
Agricultural Mechanization
Agroforestry: Complex Multistrata Agriculture
Agroforestry: Fertilizer Trees
Agroforestry: Fodder Trees
Agroforestry: Participatory Domestication of Trees
Agroforestry: Practices and Systems
Asian Aquaculture
Beef Cattle
Climate Change: Animal Systems
Climate Change: Cropping System Changes and Adaptations
Climate Change: Horticulture
Climate Change: New Breeding Pressures and Goals
Critical Tracking Events Approach to Food Traceability
Dairy Animals
Edaphic Soil Science, Introduction to
Fermentation: Food Products

PREFACE

Food is absolutely necessary for human existence, yet for most in wealthy nations it is largely taken for granted because of its abundance. Sufficient food is a concern, however, for about 1 billion of the earth's inhabitants today who often go to bed hungry. Food security in a broad sense is becoming a worry of the future for those who understand the limitations of our earth's ecosystems. Malthusian prophecies have so far been wrong, but there is growing concern that we are rapidly reaching the point where feeding the world's growing and richer population will be at the cost to our environment that is unacceptable. In the next few decades we face the challenge of growing more food, with less water, with less fertilizer on less land – because of the growth of urban areas on prime agriculture land. We also face the largely unknown consequences that global warming will have on agricultural production. During the last century agricultural scientists were able to bring cutting-edge science into traditional agricultural practices and increase food production sufficiently to prevent global food shortages. The hope that new scientific discoveries will provide the means to keep ahead of world food demand is complicated by a growing public discomfort with biotechnology being applied to food production.

The concept of services being provided by the ecosystems of the earth is a fairly recent attempt to understand and place value on functions of natural lands that have historically been assumed to have few limits. In the past, if more food was needed, new lands were converted from forests or steppe lands into farm land and new water systems developed to provide the water needed for agriculture. When human populations were low our activities were largely buffered by the abundance of forest and steppe, but too late, we are beginning to understand that these provisioning services of our ecosystems are being overused and are no longer buffered by the abundance of wild lands and waters. We are rapidly losing our planet's biodiversity, irreplaceable ground water is being unsustainably consumed, and major river systems are being overused and polluted. Our oceans, the last place on the planet that still support our hunter and gathering traditions may not be able to sustain these activities into the future. And, food production and processing activities contribute to the greenhouse gas emissions that are rapidly warming our planet. Agriculture is the single greatest user of the earth's land and water resources. In the concept of ecosystem services, provisioning or providing food for all organisms is one of the services provided by ecosystems. Human population growth has and will continue to overtax the ecosystems we inhabit. The ultimate outcome of this major diversion of nature's resources into provisioning the human species is unknown, but it is critically important for us to understand what we must do to sustain our planet.

The breakthrough discovery about 10 000 years ago that plants and animals could be bred to provide a more abundant and secure food source was the foundation upon which all other human activities were able to flourish. Activities other than finding food now became possible and our diverse cultures were able to develop because of agriculture. Until fairly recently, however, the majority of the population of most nations was still directly involved in producing food. Mechanization of agriculture and continued improvements in genetics, fertilizers, and pesticides made food production very efficient in developed nations. In the United States, the leading nation in value of agricultural exports, less than 2% of the workforce is currently employed in producing food. The United States, however, is alone among the most populous nations of the world in having such a small population employed as farmers. In countries such as China, India, Indonesia, and Nigeria the majority of people are rural and involved in agriculture either directly or indirectly. But, as food production becomes more efficient in these countries, and as wages increase in other sectors, a major shift is occurring from rural to urban occupations. This revolution is potentially as important in affecting our cultures and community structures as was the development of agriculture. Many nations are currently experiencing a very rapid transition from rural to urban living with all of the social and logistic problems associated with such rapid structural changes. While this transition in our social and cultural structures is a broad subject, it does have significant impacts on agriculture and our food systems. To mention just a few, agriculture labor, food transport, food safety, and access to healthy food.

There is genuine concern among agricultural scientists that human populations and changing diets are outpacing our ability to meet the increasing food needs of the planet. In the first iteration by Academic Press in 1994 of the *Encyclopedia of Agricultural Science*, Noble Prize Winner Normal Borlaug wrote in its forward:

> Had the world's 1990 food production been distributed evenly, it would have provided an adequate diet (2350 calories, principally from grains) for 6.2 billion people – nearly one billion more than the actual population. However, had the people in Third World countries attempted to obtain 30% of their calories from animal products – as in the United States, Canada, or European Economic Community countries – a world population of only 2.5 billion people could have been sustained – less than half of the present world population.

The issue raised by Dr. Borlaug is probably the most important challenge we face. Human behavior and the food choices of consumers will determine the outcome of the race between food supply and population. Population control has been advocated for decades, and in some cases has become part of national policy, but the world's population continues to grow. Science breakthroughs cannot solve our food security and environmental quality challenges if consumers reject food that is not traditionally produced. Likewise, if meat products and other inefficiently produced food continue to be in high demand by consumers, there will be increased pressure on our food production systems. As supplies become short, prices rise. While this may be good for farmers, high food prices and food shortages will probably undermine our efforts to preserve the

world's remaining arable land as natural lands. We must change human behavior to solve the problems we face.

Food choices, nutrition, diets, food cultures, water and air quality, GMOs, global warming, food security, and similar topics are daily in the news throughout the world. We are all concerned about these issues, yet with all of the information easily available in the popular media about food there seems to be too little informed discussion on these various topics. In planning the *Encyclopedia of Agriculture and Food Systems* the editorial committee chose to organize the topics primarily by issues, rather than to focus on a traditional topic approach. We organized the issues that would be discussed in the chapters around the broad topics of Agriculture and People, Agriculture and the Environment, Agricultural Products, Plant Health Management, Animal Health Management, and Agriculture and Science. The issues raised in this preface are the ones that we felt needed to be addressed in this encyclopedia.

The associate editors joined me in the development of topics for the encyclopedia and were responsible for working with the authors – they deserve particular recognition. I was fortunate to be joined by a very distinguished group of colleagues who, I hope, are still friends. They spent much more time and effort in bringing this project to completion than any of us anticipated. I want to thank our authors who while overly committed and overworked, fulfilled their commitments to contribute to this work. I have been impressed with the quality of their contributions. The editorial staff of Elsevier have had the professionalism and patience to work with scientists who do not work under the same time and budget constraints that the staff work. I want to particularly thank Kristi Gomez, Donna de Weerd-Wilson, and Simon Holt who, each in succession, oversaw this effort, and I especially thank the project managers, who worked directly with me, and the associate editors, Kate Miklaszewka-Gorczyca, Will Bowden-Green, and Sam Mahfoudh.

Glossary

Agricultural biodiversity (agrobiodiversity) The variability among living organisms associated with the cultivation of crops and rearing of animals, and the ecological complexes of which those species are part. This includes diversity within and between species, and of ecosystems.

Agroecosystem An ecological and socioeconomic system, comprising domesticated plants and animals and the people who husband them, intended for the purpose of producing food, fiber, and other agricultural products.

Biological diversity (biodiversity) The variability among living organisms from all sources, including terrestrial, marine, and other aquatic ecosystems and the ecological complexes of which they are part; this includes genetic diversity within species, between species, and of ecosystems (Convention on Biological Diversity or CBD, article 2).

Connectivity A measure of spatial continuity of a vegetative corridor, biological network, or matrix.

Conservation agriculture An agriculture practice that aims to achieve sustainable and profitable agriculture through the application of the three principles: (1) minimal mechanical soil disturbance, (2) permanent soil cover, and (3) crop rotation (based the Food and Agriculture Organization of the United Nations publications).

Corridor A strip of a particular type of land that differs from the adjacent land on both sides. Such corridors may have important ecological functions including conduit, barrier, habitat, and improve 'connectivity.'

Ecoagriculture An approach to the managing landscapes for the simultaneous and synergistic achievement of three sets of outcomes: (1) maintaining, increasing, or improving agricultural production; (2) conserving biodiversity and ecosystem services; and (3) enhancing human livelihoods and well-being. These elements are stitched together by institutions that support multistakeholder collaboration to achieve these outcomes.

Ecosystem services (environmental services) The benefits people obtain from natural and human-modified ecosystems, including provisioning services (goods such as food, fiber, energy, and drinking water), regulation services (beneficial processes, such as climate regulation, pollination, flood control and purification of water, and air), habitat and supporting services (such as gene pool protection) and a range of cultural services (such as aesthetic, spiritual, and cultural values).

Integrated landscape management Long-term collaboration among different groups of land managers and stakeholders to achieve the multiple objectives required from the landscape, including agricultural production, provision of ecosystem services, protection of biodiversity, and local livelihoods, health, and well-being. Stakeholders seek to solve shared problems or capitalize on new opportunities through technical, ecological, market, social, or policy means that reduce trade-offs and strengthen synergies among different landscape objectives.

Landscape A mosaic of natural and human-modified ecosystems, with a characteristic configuration of the topography, vegetation, land use, and settlements that is influenced by the ecological, historical, economic, and cultural processes and activities of the area. Both the mix of land cover and use types that make up the larger mosaic, including agricultural lands, native vegetation, and urban areas (landscape composition); and the spatial arrangement of different land uses and cover types (landscape structure) contribute to the character of a landscape. Depending on the management objectives of the stakeholders, landscape boundaries may be discrete or fuzzy, and may correspond to watershed boundaries, distinct land features, orjurisdictional boundaries, or crosscut such demarcations. Because of the broad range of factors a landscape may encompass areas ranging from 100 to 10 000 square kilometers.

Introduction and Definition

'Ecoagriculture' is an approach to managing landscapes for the simultaneous and synergistic achievement of three sets of outcomes: (1) maintaining, increasing, or improving agricultural production; (2) conserving biodiversity and ecosystem services; and (3) enhancing human livelihoods and well-being. These outcomes are achieved by institutions that support multistakeholder collaboration (McNeely and Scherr, 2003; **Figure 1**).

A 'landscape' is a mosaic of natural and human-modified ecosystems, with a characteristic configuration of topography, vegetation, land use, and settlements that is influenced by the ecological, historical, economic, and cultural processes and activities of the area. Both the mix of land cover and use types that make up the larger mosaic, including agricultural lands, native vegetation, and urban areas (landscape composition); and the spatial arrangement of different land uses and cover types (landscape structure) contribute to the character of a landscape. Depending on the management objectives of the stakeholders, landscape boundaries may be discrete or fuzzy, and may correspond to watershed boundaries, distinct land features, or jurisdictional boundaries, or crosscut such demarcations. Because of the broad range of factors a landscape may encompass areas ranging from 100 to 10 000 square kilometers (McNeely and Scherr, 2003).

'Integrated landscape management' involves long-term collaboration among different groups of land managers and stakeholders to achieve the multiple objectives required from the landscape, including agricultural production; provision of ecosystem services; protection of biodiversity; and local livelihoods, human health, and well-being. Stakeholders seek to solve shared problems or capitalize on new opportunities that reduce trade-offs and strengthen synergies among different landscape objectives. There are many different approaches to integrated landscape management, with varied entry points, processes, and institutional arrangements, but most share features of broad stakeholder participation, negotiation of objectives, strategies, and adaptive management based on shared learning (Landscapes for People, Food and Nature Initiative, 2013).

Ecoagriculture is the application of integrated landscape management in landscapes where agriculture is an important land use. Ecoagriculture involves collaboration among different groups of farmers and other land managers and stakeholders in the landscape to solve shared problems or capitalize on new opportunities. This is achieved through technical, ecological, market, or social means that reduce trade-offs and strengthen synergies among different landscape objectives (illustrated by the landscape shown in **Figure 2**). The term ecoagriculture was first coined by McNeely and Scherr (2001).

Applying the landscape approach in areas of thriving production agriculture faces additional challenges compared to forest or savannah-dominated landscapes where the approach was originally applied. Agriculture-dominated landscapes have dynamic patterns of land use change, as farmers respond to agricultural market incentives. With higher population densities, there is higher pressure on land, vegetation, and water resources, and more complex governance systems. The economic value of land for commercial crops is usually higher than for conservation. Farmers, agribusinesses, and agricultural agencies, long concerned about farmland stewardship to ensure sustainable production, have not been generally held responsible by society for stewardship of watersheds, wild biodiversity, and ecosystem functioning.

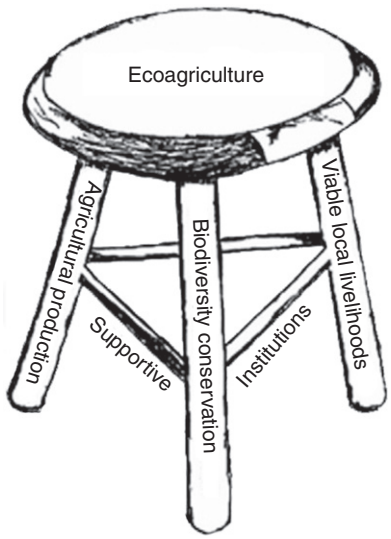

Figure 1 The ecoagriculture 'stool' illustrates the three sets of outcomes for agricultural production, environment, and human well-being in the landscape, and the institutions that support them. Reproduced from Buck, L.E., Milder, J.C., Gavin, T.A., Mukherjee, I., 2006. Understanding ecoagriculture: A framework for measuring landscape performance. EcoAgriculture Discussion Paper No 2. Washington, DC: EcoAgriculture Partners.

Evolution of Landscape Approaches

At the level of individual farms, there are numerous opportunities to increase sustainability and multifunctionality. However, sustainable field practices alone cannot usually provide the full complement of societal benefits expected from rural landscapes. A broader, spatially explicit landscape perspective is needed to address the dynamics, linkages, synergies, and trade-offs among multiple objectives, land units, and stakeholder interests, and to manage or overcome conflicts.

Landscape management concepts emerged in the 1980s with the development of the field of landscape ecology. Forman and Godron produced a seminal book in 1986 on the distribution patterns of landscape elements or ecosystems; the flows of animals, plants, energy, mineral nutrients, and water; and the ecological changes in the landscape over time (Forman and Godron, 1986). Although only marginally concerned with agriculture at first, landscape ecologists developed an analytical framework, tools and science enabling more systematic understanding and management of landscape elements for diverse functions (Dramstad *et al.*, 1996; Forman, 1995). By the 1990s, 'community-based natural resource management' approaches became more popular in the fields of forestry, watershed management and biodiversity conservation, as resource managers sought to accommodate human activities in

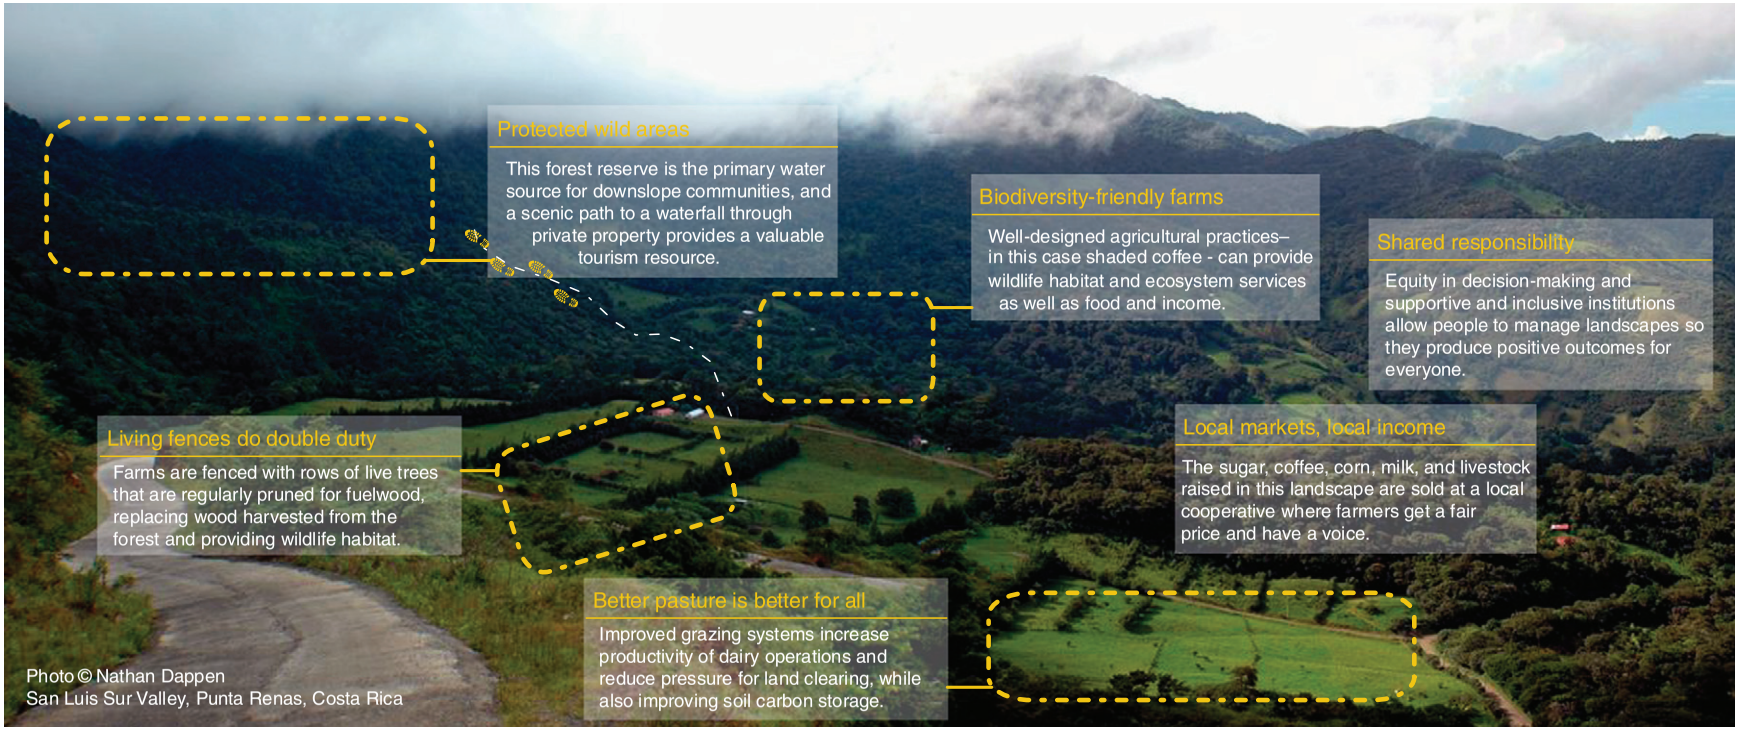

Figure 2 Achieving agricultural production, biodiversity, ecosystem, climate, and livelihood objectives in the San Juan Sur Valley landscape in Puntarenas, Costa Rica through diverse and coordinated land use activities. Photo: Nathan Dappen.

and around important habitats and protected areas. In many cases, these grew into landscape-scale strategies for action (van Noordwijk *et al.*, 2001; Sayer and Campbell, 2001).

Meanwhile, though most agricultural policy and investment still focus on field, farm, and supply chain levels, there is growing interest in landscape management systems that could simultaneously increase food production, ecosystem services, and local livelihoods. The role of healthy ecosystems in supporting and sustaining agricultural productivity is more widely recognized (Jordan *et al.*, 2007; UNEP, 2012). Societal demand for other ecosystem services is growing (Tscharntke *et al.*, 2012); given the geographic dominance of crop and livestock production in global land use, farmlands must clearly play a central role in providing them (Wood *et al.*, 2000). Analysts concerned with large-scale land-based climate change mitigation recognize the need for coordinated action across landscapes to reduce emissions, sequester, and maintain carbon storage across agriculture, forest, and conservation land uses (FAO, 2013; Scherr and Sthapit, 2009).

Varied Entry Points to Landscape Management

Landscape management strategies have emerged throughout the world to deliberately increase synergies and reduce trade-offs among rural livelihood development, agricultural production, and ecosystem conservation, through a variety of entry points.

Environmental organizations have found that spatial configuration of farmed and nonfarmed areas in a landscape is a key factor in conserving biodiversity and ecosystem services. For example, the effectiveness of fragmented protected areas is influenced by how easily wildlife can use and move through the agricultural production areas within the landscape (Blann, 2006). Thus conservation organizations are investing in landscape partnerships with farmers, ranchers, and forest managers. The managers of common property resources, such as forests, grazing lands, inland fisheries, and irrigation water find they require coordination and negotiation among institutions and stakeholders at a broader level.

Farmers, land users, and governments who depend for food security on highly degraded ecosystems are finding that ecosystem restoration can increase agricultural production, assure continued access to key water and forest resources by agricultural communities, and catalyze economic growth. Agribusiness and the food industry have begun to consider landscape management as part of corporate strategies related to risk management, supply chain reliability, regulatory compliance, and public image (Kissinger *et al.*, 2013).

Humanitarian organizations working with food-insecure farming communities have found that reducing vulnerability and increasing long-term resilience often requires action at landscape scale to manage the agricultural and natural resources on which they depend, in ordinary circumstances as well as in crises caused by disaster, famine, conflict, and climate change (Bailey and Buck, 2013). In Ethiopia, for example, the government now widely promotes landscape restoration in the highly degraded watersheds where many of the country's undernourished people reside (**Figure 3**).

These and other groups use a variety of terms for integrated landscape management that reflect their different objectives, perspectives, and initial entry points. For example, water-oriented programs may refer to 'participatory watershed management,' whereas biodiversity-led efforts are 'biological corridors.' Proponents of technological innovation around agroforestry, agroecology, permaculture, and organic agriculture are advancing their work at a landscape scale. Indigenous land managers, drawing on embedded ecological knowledge, are promoting 'indigenous territorial development,' whereas farmer-led collaborative action to restore degraded lands and waters prompted the 'landcare' movement. Scherr and Shames (2012) identified over 80 terms in active use that may be used as analogs to ecoagriculture.

Examples of Ecoagriculture Landscape Initiatives

Three examples documented illustrate the range of contexts and strategies where the ecoagriculture landscape approach is being practiced.

Figure 3 A site in Tigray, Ethiopia, where the Government of Ethiopia and the World Food Programme have restored highly degraded watersheds to achieve food security and climate resilience. Reforestation and revegetation of slopes, soil improvements, and rainwater harvesting for irrigation in microwatersheds have enabled crop intensification and greatly reduced the need for food aid during droughts (Kozar and Scherr, 2013). Photo: Raffaela Kozar.

Farming and Forest Conservation in the Central Highlands of Kenya

The Lari-Kijabe landscape in central Kenya, with one of country's last native forests is valued for its rich biodiversity and cultural heritage and for being an important smallholder agricultural production area and the catchment area for much of the capital city Nairobi's water supply. Almost half of the landscape is forested, much of which is designated important bird habitat. Over the past 15 years the community-based organization Kijabe Environment Volunteers (KENVO) has led a multistakeholder effort to mobilize local farmers and communities to balance agricultural production, livelihood security, and conservation functions by pursuing integrated approaches to forest and agricultural land management. Multisectoral development, education, research, and communication efforts by KENVO have mobilized community members and other stakeholders to restore, enrich, and protect large sections of the forest land; to sustainably intensify agricultural production systems and expand agroforestry, fish-farming, beekeeping, and other integrated practices; and to strategically locate and manage rainwater and surface water catchments to ensure adequate local access without compromising the value of the resource to downstream users (Buck *et al.*, 2011).

Farming with Wildlife in the Skagit River Delta, USA

The Skagit River Delta, approximately 100 km north of Seattle, WA in the northwestern United States harbors some of the most productive soils in the world as well as critical habitat for many wildlife species including migratory shorebirds and salmon. It is an important wintering site on the Pacific Flyway – a major travel route for birds, some of which migrate from Patagonia to Alaska – and provides crucial foraging grounds for over 100 000 shorebirds each year. The landscape also is an important food production area, providing half of the global beet and cabbage seed supply and 75% of the world's spinach. Seeing potential to align interests of conservationists and farmers, The Nature Conservancy initiated the farming for wildlife project to motivate farmers to create habitat for shorebirds on their working farms by performing 'habitat rotations' in addition to crop rotations. Groups of farmers cooperate with wildlife management authorities to create viable units of bird habitat by flooding their fields during migration season, which for more than a century have been drained of water year-round. When migration season is over, farmers drain their fields and return to growing crops. Farming for wildlife demonstrated that wetland rotations on farms can provide wildlife habitat at scale while sustaining and apparently improving soil health, reducing the need for synthetic fertilizer, and providing sufficient economic incentive to scale up the program without external payments. The enjoyment that farmers derive from managing habitat for migrating birds provides further incentive to continue their cooperative efforts (Moslemi, 2011).

Agroforestry for Watershed Protection and Reforestation in Yunnan, China

The 42-square kilometer watershed in Yangliu Township, Baoshan Prefecture in Yunnan province of Southwest China is the site of a bold and successful initiative by the World Agroforestry Center (ICRAF), China and the Baoshan Forestry Bureau to shift the Chinese government's Sloping Lands Conversion Program (SLCP) from a reforestation strategy to an agroforestry strategy that improves the livelihoods of farmers and their communities. The SLCP was created to prevent recurrence of the massive flooding that in 1998 took a tragic toll on human life and displacement, and eliminated or degraded 10 million ha of agricultural land. Its initial strategy was to deliberately take agricultural land and farmers out of production. The ICRAF–Baochan Forestry Bureau partnership launched an alternative approach to reforesting steeply sloping lands in Yunnan province that engaged village leaders in jointly developing agroforestry technologies that would integrate productive and profitable trees into villagers' farms. Building the initiative around indigenous technical knowledge to incorporate nontimber forest products into forest restoration strategies, the partners tapped into deep historical knowledge about managing and trading in medicinal herbs, indigenous tree products, and wild mushrooms of Yunnan. The Baoshan Bureau mobilized coordinated government support from diverse sectors to improve access to technical and social services by villages in the watershed and accelerate income opportunities from farming. Living standards are measurably improving, reforestation rates are rising, and investment is underway to scale up the effort to thousands of more villages in the region (Buck, 2009).

An Ecoagriculture Landscape Approach: Key Elements

Achieving multifunctional agricultural landscapes in the context of diverse and often conflicting land uses and users requires systematic action at different scales. Field experience and research on social, ecological, and production processes in landscapes have taught many lessons (e.g., Milder *et al.*, 2012a; Scherr *et al.*, 2013; Sayer *et al.*, 2013; Laterra *et al.*, 2012).

Five mutually reinforcing components comprise an ecoagriculture landscape approach: (1) agreed landscape objectives; (2) identification of synergies and trade-offs; (3) land use practices that contribute to multiple objectives; (4) markets, policies, and programs that encourage synergies and reduce trade-offs; and (5) institutions that enable collaborative planning, implementation, and monitoring among stakeholders (**Table 1**). These topics are discussed in the Sections Agreement among Stakeholders on Landscape Objectives; Management of Ecological, Social, and Economic Synergies and Trade-offs among Different Land and Resource Uses in the Landscape; Land Use Practices That Contribute to Multiple

Table 1 An ecoagriculture landscape approach: Key elements

3. Land use practices that contribute to multiple landscape objective
4. Development of supportive markets, policies, and investment
5. Establishment of collaborative processes for multistakeholder governance

Landscape Objectives; Development of Supportive Markets, Policies, and Investment Programs; and Establishment of Collaborative Processes for Multistakeholder Management.

Agreement among Stakeholders on Landscape Objectives

Landscapes reflect the management of resources by diverse stakeholders, who have different values, beliefs, and objectives for land management. Collective action toward ecoagriculture landscapes is commonly motivated by conflict among stakeholders or the inability of certain stakeholders to achieve their goals without aligned action from others. As discussed in the Sections Farming and Forest Conservation in the Central Highlands of Kenya; Farming with Wildlife in the Skagit River Delta, USA; and Agroforestry for Watershed Protection and Reforestation in Yunnan, China, in Kenya, the United States, and China, forest, biodiversity, and watershed conservation objectives initially clashed sharply with farmers' objectives. To be successful, ecoagriculture initiatives must commit to achieve multiple objectives of importance to the diverse stakeholders (**Table 2**). This commitment mobilizes interest, energy, and innovation to find solutions that are 'win-win' or at least reduce trade-offs among objectives.

Various tools and approaches have been developed to help align objectives among stakeholders. These methods foster interaction among people and organizations involved, help them look at the landscape from other perspectives, define their own goals more clearly (rather than preexisting 'positions' and the conventional solutions these assume), envisioning possible futures for their landscape and defining a few key objectives. Examples include participatory mapping, scenario development, and other tools (Stolton and Dudley, 2008; Landscape Measures Resource Center, 2013).

Management of Ecological, Social, and Economic Synergies and Trade-offs among Different Land and Resource Uses in the Landscape

Identifying and understanding beneficial and detrimental interactions among land uses and practices in some parts of the world and addressing them in ways that are acceptable to diverse stakeholders is a key driver in developing ecoagriculture landscapes. Stakeholders seek to modify agricultural practices in ways that protect biodiversity and ecosystem services (e.g., by reducing agrochemical pollution of habitats); to modify protected area management in ways that help farmers increase their production (e.g., pollinators); and to modify resource use and access to benefit local livelihoods and well-being (e.g., clean water).

Water availability is a common protagonist in landscape trade-offs and synergies. The volume and patterns of water flow, storage, and infiltration across a landscape – and thus its availability to and impacts on different water users including freshwater species – is profoundly affected by vegetative cover, physical barriers, storage, abstraction, and drainage on farms and other lands (Boelee, 2013; **Figure 4**). The design and management of irrigation systems, from sourcing to physical distribution systems to rules for water allocation and patterns of drainage, affects the availability and quality of water for agriculture, environmental, and other uses. Farmers and others users can benefit from innovations to link agriculture and water management (Macleod and Haygarth, 2010).

Table 2 Landscapes performance criteria

Conservation Goal: The landscape conserves, maintains, and restores wild biodiversity and ecosystem services
C1: Does the landscape contain an adequate quantity and suitable configuration of natural and seminatural habitat to protect native biodiversity?
C2: Do natural and seminatural habitats in the landscape approximate the composition and structure of the habitats historically found in the landscape?
C3: Are important species within the landscape biologically viable?
C4: Does the landscape provide locally, regionally, and globally important ecosystem services?
C5: Are natural areas and aquatic resources adequately buffered from productive areas and activities?
Production Goal: The landscape provides for sustainable, productive, and ecologically compatible agricultural production systems
P1: Do production systems respond to demand by internal (local) consumers and buyers, and by external buyers?
P2: Are production systems financially viable and can they adapt to changes in input and output markets?
P3: Are production systems resilient to disturbances, both natural and human?
P4: Do production practices have a neutral or positive impact on wild biodiversity and ecosystem services?
P5: Are species and varietal diversity of crops, livestock, fisheries, and forests adequate and maintained?
Livelihood Goal: The landscape sustains or enhances the livelihoods and well-being of all social groups that reside there
L1: Are households and communities able to meet their basic needs while sustaining natural resources?
L2: Is the value of household and community income and assets increasing?
L3: Do households and communities have sustainable and equitable access to critical natural resource stocks and flows?
L4: Are people in the landscape able to adapt to changes in human and nonhuman (plant & animal) population dynamics?
L5: Are households and communities resilient to external shocks, such as flooding, draught, changes in commodity prices, disease epidemics, and others?
Institutions Goal: Institutions are present that enable integrated, ongoing planning, negotiation, implementation, resource mobilization, and capacity-building in support of the goals of integrated landscape management
I1: Is there effective cross-sectoral and cross-boundary planning, monitoring, and decision-making at landscape scale?
I2: Do farmers, producers, and communities have adequate capacities to contribute to effective landscape management?
I3: Do relationships among public and civic institutions support the management of integrated landscapes?
I4: Do markets provide incentives for the management of integrated landscapes?
I5: Do knowledge, norms, and values (culture) support integrated landscape management?

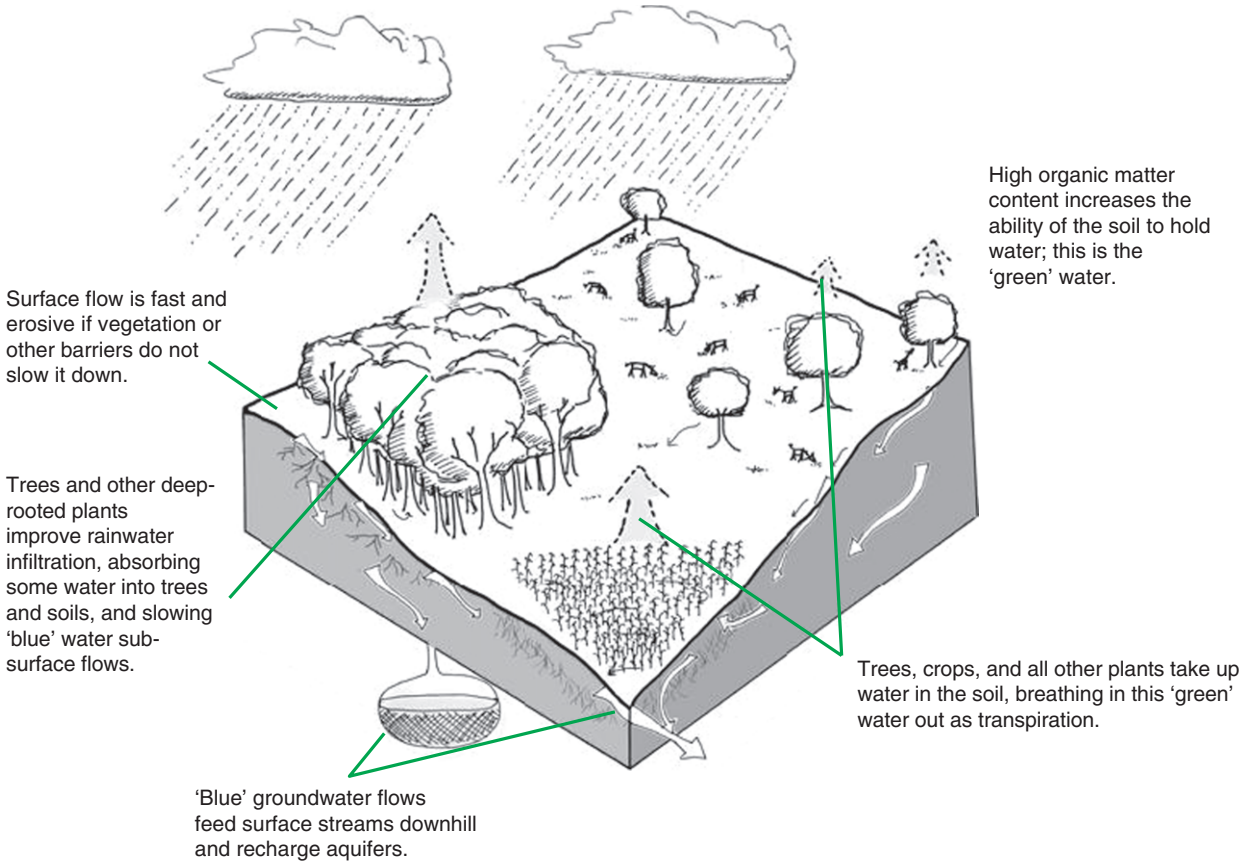

Figure 4 Water resources in a landscape include both 'blue' flows (like rainfall, streams, lakes, and underground aquifers) and 'green' flows (water stored in and moving through soils and the stems and roots of crops, grasses, trees, and other vegetation). By managing soils, vegetation, and the speed and direction of both sets of flows, the total volume of water available can be regulated. Reproduced from Buck, L.E., Scherr, S.J., 2011. Moving ecoagriculture into the mainstream. In: Starke, L. (Ed.), State of the World: Innovations that Nourish the Planet. Washington, DC: The Worldwatch Institute, pp. 15–24.

Managing perceived trade-offs between biodiversity conservation and agricultural production is another common motivator. To sustain wild species populations requires sufficient extent and configuration of natural areas, networks of suitable habitat using the noncultivated areas in and around farm, community lands, and biodiversity-compatible crop and livestock production practices (Burel and Baudry, 2005; Harvey, 2007; McNeely and Scherr, 2003; **Figure 5**). Farming communities should be able to draw some benefit from the presence of natural areas nearby and be protected from negative impacts (McNeely and Scherr, 2003). Where farmers use biodiversity-friendly agricultural practices less protected area may be needed to sustain wildlife populations (Blann, 2006). Additionally, to minimize pressures to expand production area or permit reestablishment of natural cover, it is essential to have compatible agricultural development processes in other parts of the landscape (Shames *et al.*, 2011).

Landscape-scale coordination of land management practices and investments can increase the overall effectiveness and reduce costs of climate change mitigation (Scherr *et al.*, 2013). For example, international and national reducing

Figure 5 Agricultural areas provide critical habitat for wildlife species and landscapes can be managed to enable year-round wildlife access to fresh water and food sources and protected breeding areas, in and around crop, livestock, and forest production. In Bwindi, Uganda, shaded coffee plantations are important habitats for wildlife, such as this chameleon. Photo by Jeff McNeely.

emissions through deforestation and degradation programs are shifting their strategies to a larger landscape frame, explicitly targeting action in the agricultural sector (Shames *et al.*, 2011). Risks to farmers and farming communities from climate change can be mitigated through sustainable land management practices at community as well as farm level (Nkonya *et al.*, 2011).

Stakeholders can also take advantage of the social synergies of diverse land use across the landscape. Certain areas in the landscape may be designated and managed collectively for provision of reserve food, feed, or fuel for years when communities face crop failure or interruption of markets. Differentiation of land cover can help to sustain agrobiodiversity, by maintaining social–ecological dynamics that contribute to species resilience and adaptation. Encouraging seed exchange and on-farm experimentation in interconnected farming communities can increase farmers' access to diverse varieties, knowledge, and new practices (Mijatovic *et al.*, 2013).

Scientific advances in remote sensing, resource monitoring, participatory methods, and spatial analysis are providing new tools and methods to understand spatial interactions – biophysical and socioeconomic – across the landscape (Dushku *et al.*, 2007; O'Farrell and Anderson, 2010). This knowledge can help stakeholders locate and target the most cost-effective activities, investments, and policies across a landscape. In the Lake Victoria Basin of East Africa, for example, remote-sensing methods were used to identify sites in the watershed that were generating the greatest sedimentation from soil erosion, so that investments in soil conservation could be spatially targeted, reducing overall costs to farmers and agency programs (Egoh *et al.*, 2011).

Land Use Practices That Contribute to Multiple Landscape Objectives

The basic building blocks of ecoagriculture landscapes are farming, ranching, forest, and other resource management practices on individual farms and local communities that contribute to multiple landscape objectives. McNeely and Scherr (2003) identified three key strategies that lead to ecosystem-compatible production systems: minimizing pollution; modifying management of soil, water, and vegetation resources in and around productive fields; and using farming systems that mimic components of natural ecosystems, such as species diversity, configuration, and land cover.

Over the past few decades, numerous such systems have been identified by research and farmer innovation (Buck *et al.*, 2007). Some practices incorporate advanced modern technology (e.g., precision agriculture with geopositioning tools); some are based on longstanding tradition and local knowledge (e.g., use of fertilizer trees); some incorporate both (FAO, 2011). These agroecological systems tend to have greater agricultural species and varietal diversity than conventional systems, although coexisting with greater native floral and faunal biodiversity (Delgado *et al.*, 2011; Lal *et al.*, 2011; Perfecto *et al.*, 2009).

Building soil organic matter and soil biota is a common feature. Minimal tillage, crop residue incorporation, and cover cropping practices enhance the organic matter stored in soil, while also supporting biological processes, nutrient, and hydrological cycling (Milder *et al.*, 2011; Hobbs and Govaerts, 2009). Precision methods incorporate modern technologies for fertilizer application, irrigation, land leveling, crop protection, and other agronomic techniques are helping farmers increase yields with fewer inputs and less pollution (Bongiovani and Lowenberg-DeBoer, 2004). Best practices for irrigation, water-harvesting technology, and terrace or contour farming systems contribute to improved water-use efficiency and conservation, while greatly reducing the very high greenhouse gas emissions associated with conventional irrigation systems.

Agroforestry, the intermingling of crops and trees, can address numerous functions. Productive trees and shrubs can provide diverse fruits, nuts, medicines, fuel, timber, nitrogen-fixation services, and animal fodder, whereas their canopy, roots, leaf litter, and other features provide ecosystem services benefits. Farming with perennials that develop root and woody biomass can substitute for an annual tillage regime, provide year-round ground cover, and retain organic matter and water in soil (Glover and Reganold, 2010). Systems of 'evergreen agriculture,' in which crops are produced under a managed canopy of nitrogen-fixing trees, are being adopted in many African countries (Garrity *et al.*, 2010; **Figure 6**).

Improved pasture and grassland management, including rotational grazing, regenerating vegetation, and restoring degraded land, can increase production and increase the landscape's water-holding capacity and habitat value (**Figure 7**). These strategies also contribute to climate mitigation goals through carbon sequestration in deep-rooted vegetation and soils. Converting confined livestock manure into biogas can provide added benefits of an alternative energy source with fewer negative health impacts from cooking, heating, and lighting, and reduced water pollution (Neely and Hatfield, 2007).

Such agroecological systems have been shown to increase agricultural yields, improve livelihoods, and benefit the environment in a wide range of contexts. A recent study assessed 219 peer-reviewed studies for five agroecological intensification systems, containing a total of 426 individual comparisons with conventional or baseline farming systems (Milder *et al.*, 2012b). The review found both yield and ecosystem benefits for precision agriculture and system of rice intensification (an agroecological method for increasing the productivity of irrigated rice by changing the management of plants, soil, water, and nutrients; Uphoff *et al.*, 2011) in nearly all comparisons, and in approximately half of the cases for conservation agriculture, holistic grazing management, and organic agriculture.

Local producers and communities must continuously develop, adopt, and adapt these systems at a scale that will have landscape-wide impacts. Local knowledge-sharing, training, and extension institutions need to be strengthened or developed, so land managers have strategic access to research support and specialized knowledge (Buck and Scherr, 2011).

Development of Supportive Markets, Policies, and Investment Programs

Supportive market institutions, public policies, and investment programs can encourage synergies and reduce trade-offs among the agreed landscape objectives. Widespread adoption

Figure 6 Evergreen agriculture combines annual crops with over-story trees that benefit crop production as well as landscape goals, such as wild biodiversity, soil quality, and water infiltration. Photo by ICRAF.

Figure 7 Intensive rotational grazing systems, such as this one in Washington County, VA, USA, increase meat and milk productivity by increasing feed resources at low cost, while also improving above- and below-ground vegetation with benefits for rainfall infiltration, carbon sequestration, storage, and biodiversity. Photo by Jeff Vanuga.

of multibenefit production systems depends in part on clear financial incentives for farmers, ranchers, and forest managers to do so. In some cases, the profitability (from lower costs, higher yields, or quality) and reduced risks of these systems provide sufficient incentive. But often changes in market institutions are needed as well. Diverse strategies are being used to link market development with landscape approaches (Scherr *et al.*, 2011).

In some cases, markets for new and minor products can incentivize the diversification of production systems. For example, there are now widespread efforts to domesticate indigenous fruit and nut trees that are traditionally and culturally important to produce marketable products. New supply chains, quality standards, and processing methodologies may need to be developed for products that are being sustainably harvested from wetlands or forests to supplement local incomes.

Entire supply chains for some crop and livestock products may need to be restructured. Market signals are needed to incentivize sustainable sourcing. To provide these market

signals, ecostandards, ecocertification, and ecolabeling systems have emerged (Millard, 2007). Whereas organic certification has been dominant, commodity roundtables have developed other certification systems for more sustainable palm oil, soy, biofuels, cocoa, sugar, and more recently for rice and livestock. Numerous other certifications for environmental and social standards have arisen. By 2010, the global market for certified agricultural products was estimated to be over US$64 billion, of which organics accounted for more than US$50 billion. Such markets are projected to grow at 15% annually in the short term (Potts *et al.*, 2014). New models are being developed to make certifications easier for smallholder farmers to use (Blackmore *et al.*, 2012).

Although focused initially on farm-scale impacts, sustainability standards have begun to address landscape-scale impacts. For example, company members of the Consumer Goods Forum, worth almost US$2.8 trillion of processed products, committed in 2010 to help achieve zero net deforestation by 2020, by eliminating from their supply chains all products associated with tropical deforestation (The Consumer Goods Forum, 2010). Landscape labeling approaches are being developed that seek to turn unique landscape qualities into a marketing advantage for diverse products.

Other market mechanisms are being developed to pay farmers and communities directly for using production systems that contribute to ecosystem services, particularly agroecological practices (Kinzig *et al.*, 2011; Lipper and Zilberman, 2009). Already worth billions of dollars, a majority of payments are by public agencies, but increasingly, private companies or conservation groups are paying farmers directly, such as water bottling companies seeking to protect water quality. The design and payment allocation of such systems is increasingly informed by a landscape perspective (Milder *et al.*, 2010). Spatial or ecosystem criteria can be added to develop marketing strategies that target specific ecological niches and social groups in a landscape (Scherr *et al.*, 2011).

Some agribusiness actors are integrating landscape thinking into their supply chain strategies. A recent scoping exercise found 27 international companies that had begun to adopt landscape approaches (Kissinger *et al.*, 2013; **Figure 8**). The most common rationales were mitigating local community and operational risks, including secure access to water and mitigating climate change; value chain efficiency; and voluntary standards compliance. The most common modes of engagement were: value chain interventions that include landscape elements (such as ecocertification, which often requires the identification of high conservation value lands at regional scales); regional producer support programs across communities; and payments for ecosystem services (especially carbon or water finance).

Public policies and programs can be used to establish, develop, and scale up ecoagriculture. Decentralized governance enables local stakeholders to control key planning decisions, incorporating local needs and priorities. Secure systems of use, access rights, and property rights provide farmers and communities the necessary incentive to manage their lands sustainably, and in many landscapes, achieving multiple product and service functions may require reforming land, resource tenure, and access rights (Mwangi *et al.*, 2012; WRI, 2005).

Coordination of policies is required, with mechanisms to encourage regular engagement between agriculture, forest, environment, climate, health, and rural decision-making institutions. Public investment programs must be structured to enable intersectoral funding of activities that have multiple cobenefits (Shames *et al.*, 2012). Financing may also be needed to cover early investments costs at farm or landscape levels. Around the world, countries seeking to support the multifunctionality of agriculture are shifting in the main focus of subsidy programs from production to the social and environmental functions of agriculture. An ecoagriculture lens for development planning can highlight alternative investment strategies, as illustrated for biofuel development (Milder *et al.*, 2008) and agriculture green growth strategies in Tanzania (Milder *et al.*, 2013).

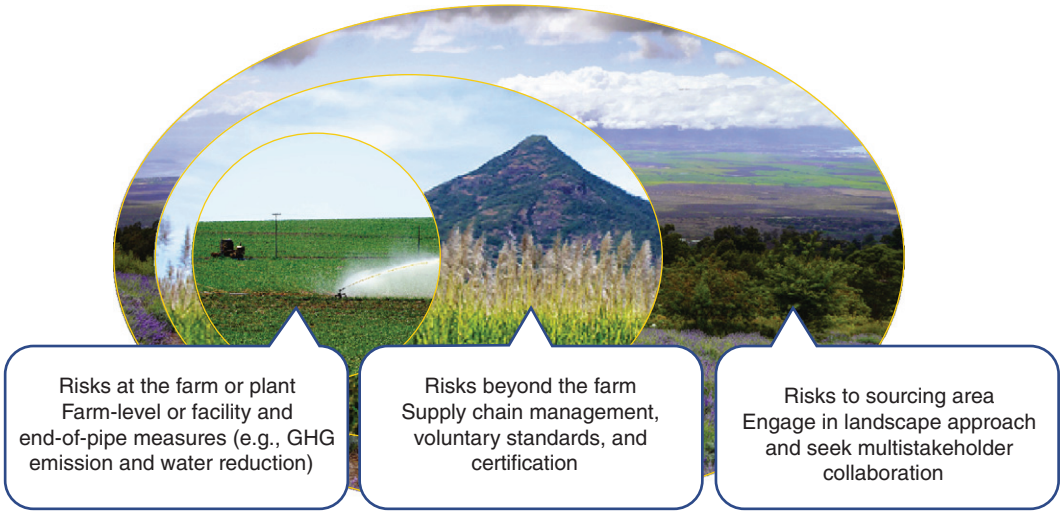

Figure 8 Companies become engaged in landscape approaches when business risks must be managed beyond the farm and supply chain scales. Adapted from Kissinger, G., Brasser, A., Gross, L., 2013. Reducing risk: Landscape approaches to sustainable sourcing. EcoAgriculture Partners for the Landscapes for People, Food and Nature Initiative. Washington, DC: EcoAgriculture Partners.

Establishment of Collaborative Processes for Multistakeholder Management

Further elaboration of the four elements of ecoagriculture (described in the Sections Agreement among Stakeholders on Landscape Objectives; Management of Ecological, Social, and Economic Synergies and Trade-offs among Different Land and Resource Uses in the Landscape; Land Use Practices That Contribute to Multiple Landscape Objectives; and Development of Supportive Markets, Policies, and Investment Programs) requires coordinated decision-making and action by stakeholders from public, private, and civic sectors who bring diverse knowledge and interests to planning and managing integrated landscapes. Such processes serve as a means to develop partnerships, share knowledge, build coalitions, and pool investments.

Landscape management initiatives need to recognize the presence of complex overlapping jurisdictions, and the uneven distribution of decision-making authority among actors with interests in the outcomes. Research points to the benefits of establishing collaborative, adaptive management processes that seek to include a broad spectrum of participants, women and men alike, in thoughtfully designing change strategies that are implemented incrementally, step by step. Such processes are structured to engage actors with diverse perspectives to envision optimal futures and then design innovative interventions, monitor their implementation, observe their effects, and learn from the experience. Through this social learning, viable ways of capturing synergies and reducing trade-offs become apparent, innovations that address the interests of multiple stakeholders become better understood and appreciated, mistakes are made and mitigated, trust is built, and commitments are made to continue working together toward shared goals for the landscape (Sayer *et al.*, 2013; Buck and Scherr, 2009).

Ecoagriculture strategies for building multistakeholder management are explicit about the interests, rights and roles of farmers, pastoralists, fisherfolk, and other producers as well as the agricultural research, extension, finance, and administration actors who support them. Management strategies strive for inclusive and transparent governance, or ways and institutions through which citizens and groups express their interests, exercise their rights and obligations, mediate their differences, and build trust and cooperation (Colfer and Pfund, 2011).

The Landscapes for People, Food and Nature Initiative's reviews of integrated landscape initiatives found an average of 9.4 stakeholder groups representing an average of 3.8 sectors per initiative, whereas in Latin America and the Caribbean an average of 10.5 stakeholder groups are involved representing an average of 4.1 sectors (**Table 3**). More than 83% of initiatives included local farmers or producers association, the most

Table 3 Sectors and stakeholders engaged in integrated landscape management initiatives in Africa, Latin America, and the Caribbean

	Africa	*Latin America and the Caribbean*
Number of integrated landscape initiatives surveyed	87	104
Countries	33	21
Average number of stakeholder groups	9.4	10.5
Most frequently involved stakeholder groups (in more than 70% of initiatives)	Local farmers' or producers' associations (83%), local government leaders (80%), extension officers (71%), and local nongovernmental organizations (NGOs) (71%)	Local farmers' or producers' associations (86%), local government leaders (82%), local NGOs (78%), district-level government offices (75%), local or national research center or university (74%), and state or provincial government offices (71%)
Other stakeholder groups involved (in fewer than 20% of initiatives)	Representatives of landless people groups (13%), In-country agribusiness groups (8%), logging or forest products industry members (5%), Mining, oil or gas industry members (3%), and foreign agribusiness groups (0%)	Representatives of landless people groups (18%), foreign agribusiness groups (7%), logging or forest products industry members (20%), and Mining, oil or gas industry members (7%)
Average number of sectors	3.8	4.1
Most frequently involved sectors (in more than 50% of initiatives)	Natural resources conservation or environment (in 86%), agriculture (in 80%), and forestry (in 57%)	Natural resources conservation or environment (in 89%), agriculture (in 75%), forestry (in 53%), and tourism (in 52%)
Other sectors involved (in fewer than 50% of initiatives)	Livestock (in 49%), education (in 30%), tourism (in 25%), health (18%), roads, transportation or infrastructure (in 16%), and energy (in 14%)	Education (in 47%), livestock (in 39%), health (in 26%), energy (in 16%), and roads, transportation or infrastructure (in 13%)
Percent of initiatives that aimed to form a new coordinating body	53%	50%
Percent of initiatives that reported improved coordination and cooperation among stakeholder groups and sectors	77% among stakeholder groups and 43% among sectors	80% among stakeholder groups and 55% among sectors

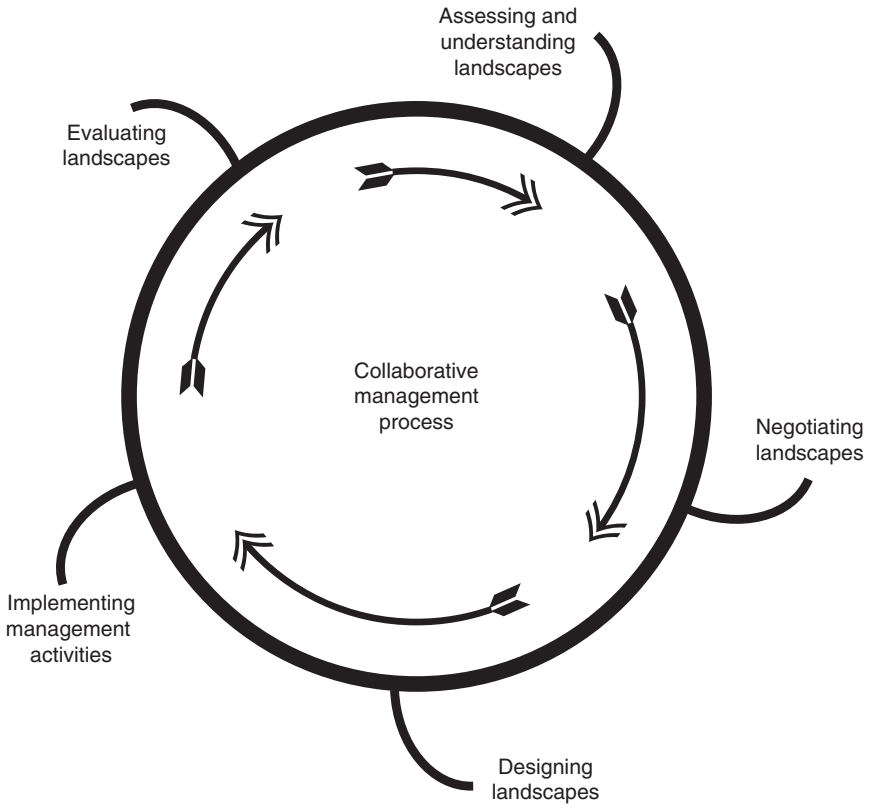

Figure 9 Collaborative processes for integrated landscape management move through typical cycles of adaptive management: Assessment of landscape issues, negotiation over objectives, design of stakeholder actions, implementation, and monitoring, followed by reassessment, and redesign.

common category of stakeholders. Other sectors most frequently involved are natural resources, conservation or environment, forestry, and tourism (Estrada-Carmona *et al.*, 2014).

Colfer *et al.* (2011), who examined landscape governance in numerous tropical countries, found that despite the inherent complexities a dual emphasis on bottom-up and top-down approaches leads to the best chances for long-term success. This dual approach was more viable than prioritizing one approach over the other. Alexandra (2012) stresses the rich learnings from recent experience in bioregional conservation planning, natural resource management, landcare, and water reform as a basis for building capacity for integrated and adaptive resource management. Primmer and Furman (2012) emphasize landscape governance for operationalizing ecosystem services approaches, and stress the importance of moving from sector-based to integrated approaches by deliberately building on governance arrangements that are geared toward sustainability.

In some cases, community-based organizations or farmer groups find they can better meet their goals through collaboration with other stakeholders or sectors and initiate a process of landscape-level learning and negotiation that eventually leads to commonly accepted roles and rules of decision-making (Buck *et al.*, 2010). As primary managers and stewards of land and resources, farmers and communities must be involved in landscape initiatives as stakeholders and partners, not simply as 'beneficiaries' or 'targets.'

Because ecoagriculture landscapes are transformed over a generation or more, not through a single short-term project, collaborative management systems must enable stakeholders to assume long-term perspectives by continuously planning, monitoring, and adapting strategies to address dynamic social, economic, and ecological conditions (**Figure 9**). Leaders must enable their constituents to understand and communicate the multiple benefits that ecoagiculture landscapes stand to generate: including yield improvements, food and energy security, human health, biodiversity conservation, and other ecosystems services, and to make good use of landscape monitoring systems that are being developed to monitor suites of objectives over time (Buck *et al.*, 2006; Kinzig *et al.*, 2011; Landscape Measures Resource Center, 2013; Sachs *et al.*, 2010; Vital Signs, 2013).

Current Scope and Scale of Integrated Landscape Initiatives

In regions with high pressure on land, multifunctional landscapes are increasingly seen to play a crucial role in reducing conflicting claims on land, while meeting societal demands for multiple goods and services from rural landscapes (Brandt and Vejre, 2004; Smith *et al.*, 2010). Landscape approaches involving farmers and agriculture are being applied in agricultural policies and programs, as more communities, governments, and organizations find they cannot meet their needs

and objectives through strategies that focus only on specific sectors like agriculture, forestry, or water.

As shown in **Table 3**, recent surveys have documented over 107 integrated landscape initiatives in Latin America (Estrada-Carmona *et al.*, 2014) and over 85 in Africa (Milder *et al.*, 2014). In Asia and the Middle East, other research has documented 21 longstanding landscape management systems where humans have developed integrated strategies for maintaining agricultural productivity and rich natural ecosystems (Ichikawa, 2012). Many of these are in places where high levels of poverty coincide with critical conservation priorities. Meanwhile, in North America, Europe, Australia, and Japan, many integrated landscape approaches are being developed to meet challenges of water quality, resolve water conflicts, manage commercial agriculture in environmentally sensitive areas, and sustain cultural aspects of rural landscapes (Daugstad *et al.*, 2006; Crossman *et al.*, 2010; Gascoigne *et al.*, 2011; Plieninger and Bieling, 2012). The need to manage landscapes in an integrative way was picked up in the political arena with several comprehensive spatial planning strategies in Europe and a shift toward farm subsidies for practices that support ecosystem services and biodiversity, rather than increasing production (e.g., Dijst *et al.*, 2005; Cairol *et al.*, 2009; Vejre *et al.*, 2010).

Some landscape initiatives are led by farmer or community groups who band together to solve problems that transcend the purview of single organizations. Others have been organized through government initiatives, programs of nongovernmental organizations (NGOs), or new market initiatives. Landscape approaches have been applied by many of the world's leading international organizations, funding agencies, and NGOs dedicated to agriculture, rural development, watershed management, and ecosystem conservation. For instance, in Africa, the continent-wide TerrAfrica program is harnessing several billion dollars in government support and donor funding, with high-level political commitments, to promote sustainable land management at large scale, including through landscape approaches.

Several networks have emerged to help support and share information among landscape initiatives. The Ibero-American Model Forest Network supports 28 landscapes in Latin America, the Caribbean, and Spain (International Model Forest Network, 2010). Landcare International facilitates farmer groups, in Australia, Africa, and Asia, to integrate agricultural production, water, and wildlife management (Catacutan, 2010). The International Partnership for Satoyama Initiative is supporting community-managed landscapes, drawing inspiration from traditional Japanese landscape approaches. The program of Globally Important Agricultural Heritage Systems supports the continued vitality of 19 socioecological landscapes developed by traditional societies, and assists them to meet new challenges (FAO, 2012). The Landscapes for People, Food, and Nature Initiative has set up a knowledge-sharing network for landscape leaders around the world (Landscape strategies are being incorporated into the Convention on Biological Diversity's work on the ecosystem approach in agricultural landscapes (Shames and Scherr, 2009), and United Nations Environment Programme's (UNEP's) work promoting an ecosystem-based approach to food security (Munang *et al.*, 2013). The United Nations (UN) Framework Convention on Climate Change is sponsoring its first Global Landscapes Forum in 2013 .

In Central America, heads of state for eight countries, including the Dominican Republic, have endorsed and are now implementing in 29 landscapes a territorial approach to rural development that supports participatory planning for agriculture, environment, health, human development, and climate change in an integrated way (IICA, 2010). In the West African Sahel, a multinational coalition is working with communities to restore woodlands, protect and enrich agricultural soils, and reduce poverty in landscapes stretching across a belt 7700 km long, from Senegal in the west to Djibouti in the east (World Bank, 2011). The new Global Partnership on Forest and Landscape Restoration is aiming to restore 150 million ha of degraded land, of which 50 million targets agricultural landscapes in the tropics (GPFLR, 2013). The United Nations Development Programme (UNDP), with support from the government of Japan, began in 2011 the UNDP Satoyama Initiative, which is assisting community-based agricultural landscape initiatives in 15 developing countries. The Global Environment Facility is implementing integrated landscape programs with strong agriculture and food security components in focal areas of land degradation, biodiversity, international waters, and climate change (Bakarr *et al.*, 2013).

In 2004, the European Landscape Convention came into effect, a Europe-wide concept centering on the quality of landscape protection, management, and planning and covering the entire territory, not just outstanding landscapes (Council of Europe, 2004). In 2012, a group of African heads of state adopted the Gabarone Declaration, which includes explicit mention of integrated landscape approaches for agriculture, environment, and development (Gaborone Declaration, 2012). In June 2012, participants in the Nairobi International Forum endorsed a Call to Action to promote Landscapes for People, Food, and Nature (Landscapes for People, Food and Nature Initiative, 2012).

Current State of Research on Ecoagriculture Landscape Management

As action on the ground is accelerating, the evidence suggests that ecoagriculture landscape approaches have promising potential to reshape land use at local, national, and global scale. Recent scientific articles are refining conceptual approaches and expectations from integrated landscape management (Menz *et al.*, 2013; Scherr and McNeely, 2008; Cunningham *et al.*, 2013). Authors have stressed a range of interdisciplinary future research needs (Aggarwal *et al.*, 2010; Carpenter *et al.*, 2009; Rounsevell *et al.*, 2012; Sayer *et al.*, 2013; and Veldkamp *et al.*, 2011). Current landscape science covers the understanding, explorations, and acknowledgment of many multidisciplinary issues like the spatial multilevel character of landscape processes and governance systems (Veldkamp *et al.*, 2011), the behavior of individuals and society regarding land management decisions (Matthews *et al.*, 2007), the ways in which people and land are teleconnected to the broader world (Lambin and Meyfroidt, 2011), and the future and past drivers of landscape change (Claessens *et al.*, 2009).

However, there are many remaining challenges to support the mainstreaming of ecoagriculture landscape approaches. The quantitative evidence of impacts of landscape-scale interventions remains weak (EcoAgriculture Partners, 2012). Also needed is a better understanding and evidence of the impact of agricultural practices, level of intensification, and temporal aspects of agricultural systems on a broad range of landscape benefits. Also, new research is needed to better understand the scientific principles and processes underlying ecosystem-friendly farming systems, and ways to improve their management and performance across different spatial and temporal dimensions.

The proliferation of spatial data sources, available online as open-access resources, should allow for better assessment of the condition, use, and changes in resources and functions across the landscape. Paired with appropriate modeling and decision-support tools, data access enables landscape managers and stakeholder groups to evaluate and predict the effects of alternative courses of management actions, select the most suitable approaches, and monitor the impacts (Kok and Veldkamp, 2011; Kenwarda *et al.*, 2011).

Another focus area for research is to gain a better understanding of how local agricultural decision-making takes place in reaction to macro-level economic and price dynamics and to understand the role of incentives and investments to enhance a synergetic supply of benefits from rural landscapes (Bryan, 2013). To support decision-making, landscape science has so far mainly developed methods to describe landscape processes. Normative methods that can prescribe pathways to desired outputs are not yet readily available. Such prescriptive methods are crucial to identify and plan for alternative development pathways.

Several national research programs are advancing landscape systems analysis, such as the Commonwealth Scientific and Industrial Research Organization in Australia, Leibniz Center for Agricultural Landscape Research in Germany, and Cornell University's Ecoagriculture Working Group in the United States. The Consultative Group for International Agricultural Research, focusing on science-for-development, has established a number of Collaborative Research Programs with strong landscape science components. Relevant approaches to research partnerships are being developed (Tomich *et al.*, 2007).

The Landscapes for People, Food, and Nature Initiative is undertaking collaborative scoping studies to synthesize and disseminate the current state of knowledge relevant to practitioners. Generally, however, the practical research base to support ecoagriculture landscape management is still at an early stage. Research priorities for development include generating more systematic evidence on:

- best agricultural and land management practices for implementing ecoagriculture in different (changing) biophysical and social contexts, uncertainties, including evidence about the benefits and costs (initial investments and trade-offs) of integrated landscape approaches;
- underlying field-to-farm-to-landscape processes and interactions, and the functioning of farming and natural resource management systems to realize synergies and reduce trade-offs across a range of benefits and beneficiaries;
- implementation strategies for successful landscape initiatives. Methods for facilitating multistakeholder landscape assessment, setting of desired outputs/vision, planning, negotiation, and monitoring require further development; and
- how policies, incentives, and investment can create an enabling environment for integrated landscape management and for realizing new sources of synergy in rural landscapes.

Glossary

Ambient pollution The amount of a contaminant present in an environmental medium, such as air or water; usually expressed per unit volume. Ambient pollution is the end result of pollution discharges after mixing and natural degradation processes take place.

Depletable resource A substance from which economic benefits are produced but which has a finite supply within a human timescale. For example, most mineral resources are considered depletable, although technological advances and recycling may increase human capacity to exploit them. Radio wave bands, although not material in nature, may also be considered depletable resources, given limitations on the available spectrum.

Economic efficiency The condition under which it is not possible to reallocate resources between uses, either in production or consumption, so as to increase overall value. For priced resources, an economically efficient allocation satisfies the condition that the ratio of incremental benefits from the use of any two resources equals the ratio of their prices.

Economic sustainability The capacity to endure economically, encompassing not only the resources necessary to sustain well-being at levels at least comparable to the present, but also social, cultural, and ecological capacities to adapt as conditions change.

Economic welfare The well-being achieved through enjoyment of goods and services realized through economic activity.

Ecosystem services Resources and processes supplied by ecosystems. Examples include the pollination services provided by insects, degradation services provided by microorganisms feeding on pollutants, and esthetic and genetic preservation services provided by nature reserves.

Externality A consequence of an activity or transaction that imposes costs or benefits on a party without that party's consent. For example, industrial smoke may increase lung discomfort and disease in nearby residents or a conservation area may provide recreational and esthetic benefits to nearby residents without cost.

Point and Nonpoint source pollution Point source pollution emanates from sources that are easily identified and monitored, such as smokestacks or waste discharge pipes. Nonpoint pollution originates from diffuse sources, such as soil particles or fertilizer emanating from land, in contrast to discharges from discrete and easily monitored sources like smokestacks or effluent pipes. The diffusion of sources complicates monitoring, measurement, and assignment of responsibility.

Public good A valuable material or service that satisfies two conditions: (1) nonexcludable – potential beneficiaries cannot effectively be excluded from use and (2) nonrival – one user's enjoyment of the good does not diminish its availability to others. Examples include air quality, national defense, knowledge, and mosquito control.

Renewable resources A substance from which economic benefits are produced and which reproduces or replenishes relatively quickly through natural processes. Examples include wildlife, vegetation, and wind.

Introduction

Until the early 1970s, agricultural policies in developed countries were largely intended to serve policy objectives related to agricultural productivity, farm income, commodity prices, agricultural trade, and rural economic vitality. Environmental externalities and resource degradation associated with agricultural production were generally unrecognized or not considered public policy issues. Natural resource policies relating directly to agriculture were intended to facilitate access to and to protect the quality of land and water resources essential to agricultural production. In the United States, for example, the federal government invested in the development of reservoirs and irrigation systems in the first half of the twentieth century essential to large-scale agricultural development in the arid West. These systems are operated by the Federal Bureau of Reclamation (FBR) and have historically offered water for agriculture at prices that do not cover costs. The United States established the Soil Conservation Service (now the Natural Resource Conservation Service) to administer soil and water conservation programs in the 1930s with the primary objective of protecting agricultural productivity and sustaining agriculturally dependent rural economies. The catalyst for these programs was the 'Dust Bowl' of the 1930s, named for giant dust storms originating from soils disturbed through the conversion of native grasslands to cultivated crop land. Policies directed at inputs or activities that are today considered important determinants of agri-environmental externalities existed, but served other objectives. For example, national insecticide regulation programs initiated with the Federal Insecticide Act of 1910 were to protect farmers from fraud in the insecticide supply chain.

The goals of agricultural resource and environmental policies have shifted significantly since the late 1960s from agricultural production to environmental protection. In the 1960s food was abundant, agriculture was declining in importance as

 doi:10.1016/B978-0-444-52512-3.00122-4

a source of income and employment in many countries, the environment was emerging as a major public policy issue, and agricultural practices were recognized to pose significant environmental risks. Harm to fish, wildlife, and human health resulting from pesticides was an early concern and led to policy initiatives to regulate pesticide use for environmental protection. In the United States, for example, the 1972 Federal Environmental Pesticide Control Act, which superseded the 1910 Federal Insecticide Act, made environmental and public health protection the primary objectives of pesticide regulation, and transferred regulatory responsibility from the US Department of Agriculture to the newly created US Environmental Protection Agency. Fertilizers, pesticides, animal wastes, and eroded soils were increasingly recognized as major causes of water pollution in agricultural regions of Europe and North America, leading to initiatives to protect water quality from agricultural production. In the United States, water quality, and subsequently other environmental objectives have largely displaced traditional soil and water conservation objectives in federal agricultural conservation programs; large confined animal enterprises are regulated as industrial polluters. The proenvironmental evolution of resource-oriented policies has also recognized beneficial agricultural impacts. In Europe and North America policies protect agricultural land from urban development to conserve cultural resources and to provide rural amenities. The elevation of the environment in contemporary agricultural policy has also led to some rethinking of traditional proagricultural policies, as some have been recognized as encouraging environmental degradation and inefficiency in the use of scarce natural resources.

This article examines the economic foundations for contemporary analysis of agricultural policies related to natural resources and the environment. It begins with an economic framework for thinking about agriculture's relationship to natural resources and the environment, and then elaborates that framework by introducing pertinent economic concepts. These concepts are applied to various environmental problems and natural resource issues associated with agriculture, including water pollution and use, air quality and climate impacts, biodiversity conservation, and soil quality.

Agricultural Production and the Environment

Traditionally, agricultural production would be described by economists as involving the application of labor, capital, fuel, and material inputs to land to produce conventional agricultural commodities. Land provided space and access to essential natural resources – soils, water, nutrients, and solar energy. The implications of agricultural land scarcity, in both quantity and quality, for the welfare of humans were among the first concerns of Thomas Malthus, David Ricardo, and other early founders of modern economics writing in the early days of The Industrial Revolution. These concerns were allayed by the migration of European populations to new continents, the migration of people from agricultural occupations and locations to urban areas and industrial occupations, and technological change that diminished the land intensity of agricultural production.

Advances in environmental science since the 1960s have led to new conceptions of the relationship between land use, landscapes, the products and productivity of managed and unmanaged ecosystems, and human well-being, and to a new ecological paradigm for conceptualizing these relationships. This paradigm, introduced in the 1990s, views managed and unmanaged ecosystems as providers of ecosystem services. Ecosystem services are benefits that people receive directly or indirectly from ecosystems (Daily, 1997; MEA, 2005). They are broadly classified as provisioning services (e.g., food, fiber, fuel, and water), regulating services (e.g., regulation of floods, drought, land degradation, and disease), supporting services (e.g., soil formation and nutrient cycling), and cultural services (outdoor recreation, esthetics, and nonmaterial benefits). Within this paradigm, agricultural production takes place within agroecosystems that encompass crops, pasture, livestock, other flora and fauna, soils, water, and the atmosphere and their interactions on the land on which agricultural activity takes place and beyond to encompass other systems affected by farming activity. These agroecosystems are contained within and interact with larger landscapes, which include uncultivated land, drainage networks, and wildlife. The emergence of agroecosystems as a typology reflects the profound impact that agricultural activity often has on the structure of the surrounding landscape (Heinz Center, 2003; MEA, 2005). Within the taxonomy of ecosystem services, agroecosystems serve first and foremost to provide 'provisioning services,' which are the food, fiber, and energy products from agricultural enterprises (**Figure 1**). Agroecosystems depend on supporting and regulating ecosystem services for their productivity, and agricultural production activities in turn influence these and cultural services (Power, 2010; Swinton *et al.*, 2007; Zhang *et al.*, 2007).

The environmental consequences of agriculture are influenced by a variety of factors. One is the amount of agricultural activity affecting the environment, and one indicator of this is the amount of land in agriculture. However, there is much more than agricultural land area that is important. Other factors include the characteristics of farming systems (e.g., tillage intensity, chemical use, nutrient management, animal intensity, and crop diversity), characteristics of soils, climate, and topography, the ecological structure of the agricultural landscape, and the types and sensitivity of the environments that are affected by agriculture. These factors are not independent, and in large and highly geologically, topographically, climatically, and ecologically diverse landscapes can vary greatly across space.

The ecosystem services framework can be merged with the economic theory of public goods and externalities to offer a modern conception of agricultural production that is useful for economic and policy analysis (**Figure 2**). Agricultural production involves combining private market goods (labor, capital, fuel, and materials inputs) with nonmarket public or quasi-public goods (ecosystem services) to produce private market goods (commodities – provisioning services). However, agricultural land and production activities also cause or influence the volume and composition of various material flows from farms to the environment (odors, pests, pesticides, nutrients, carbon, runoff, dust, and smoke) that affect environmental public goods (air quality, water quality, nutrient

Guidelines for Cost-Effective Agri-Environmental Policy Measures. Paris: OECD Publishing and Organization for Economic Cooperation and Development (OECD), 2013. Providing Agri-Environmental Public Goods through Collective Action. Paris: OECD Publishing.

cycles, climate, etc.). Agricultural land and production activities also have nonmaterial flows (sights and sounds) that affect environmental public goods (visual amenities and noise). Being nonexclusive (people cannot be excluded from using them) and nonrival (consumption by one person does not reduce the amount available to others), access to and the quantity of environmental public goods cannot be determined efficiently by private property rights. In consequence, the material and nonmaterial flows affecting these goods are traditionally nonmarket goods. Agricultural production has traditionally had open access to these goods as a presumptive property right (Bromley and Hodge, 1990). The joint production of a public good (or bad) with a market good is a classic source of economic externality (Cornes and Sandler, 1996). Markets provide agricultural producers with prices for traditional market inputs and outputs, but not for jointly produced nonmarket outputs that affect the off-farm environmental conditions. If input and output prices reflect marginal social costs and marginal social value, and if agricultural producers are perfectly competitive profit maximizers, then the expected result without policy intervention is an oversupply of negative environmental externalities and undersupply of beneficial environmental externalities. Economic analysis of agricultural externalities typically proceeds under the assumption that these conditions apply. However, alternative conditions can be important to the nature and economic cost of agricultural externalities. The nature, magnitude, and location of externalities may be influenced by distortions in input and output markets, imperfect information about technologies, and imperfections in property rights for land, water, and other market goods.

An important consideration in the creation of agricultural externalities is the distortion of prices paid and received by farmers as a result of public policies (Just and Antle, 1990; Lichtenberg and Zilberman, 1986). Agricultural production is typically competitive, but agricultural markets are often distorted by public policy interventions. In developed countries, these generally aim to increase farm profits by increasing output prices and reducing input prices for producers. The impact on externalities depends on the effects of price changes on the mix of agricultural outputs, the mix of inputs, the scale and location of production, and the relationship between these factors and agricultural externalities. Policies that generally increase prices received by producers above market prices without imposing restrictions on output will encourage higher production and will increase (decrease) externalities that are positively (negatively) correlated with production. The reverse is true for policies that increase prices by restricting production (e.g., output quotas). Policies that reduce the prices of inputs below their social costs will result in higher input use, and to the extent that lower prices induce higher production, increase (decrease) externalities that are positively (negatively) correlated with the scale of production. Technologies and inputs vary in their effects on the environment, and their utilization varies across commodities. For example, some commodities are more pesticide and nutrient intensive than others. Some farming systems are more tillage intensive than others. Finally, some regions are more ecologically sensitive to agricultural production than others. Accordingly, policies that influence the composition of agricultural output, the location, technologies, and composition of inputs will affect the composition and cost or benefit of agricultural externalities.

The direction of impact of agricultural production on environmental conditions in specific locations depends on the specific practices employed. For example, some agricultural practices are more harmful to air or water quality, biodiversity, or global climate than others. In consequence, changes in agricultural practices can increase or decrease the supply of ecosystem services. An alternative comparison is between agricultural and nonagricultural land uses. Agriculture is generally ecologically disruptive compared with forests or native landscapes. However, urban land uses generally pose a far greater risk to air and water quality, and ecosystem services generally, than agricultural production in the same location. Accordingly agricultural land use can be viewed as increasing the supply of ecosystem service when compared with some alternatives and the opposite when compared with others.

Key Concepts in Environmental and Resource Economics

Efficiency in Markets

A central focus of economics is the efficient allocation of resources to supply goods and services to satisfy the demands of consumers living now and in the future. Natural resources are treated as goods that yield direct consumption benefits (water for human consumption, recreational benefits from the use of land) or as inputs in the production of other goods that are ultimately consumed (crops and forest products). That is, their value is viewed from the perspective of their direct or indirect consumptive utility, or preference satisfaction, for individuals. Economics is sometimes criticized for its focus on consumption. However, it should be borne in mind that this includes the ability of individuals to 'consume' health care, education, and a range of other services and to be able to exercise choice in the use of their time for leisure and recreational pursuits, that is, to have access to the things that many would associate more broadly with the 'quality of life.' Besides, production is not limited to physical goods. It includes services provided by natural resources, such as environmental amenities, that are valued by people. One of the implications of this is that when consumptive resource use in agriculture is consistent with the maintenance of a given ecosystem (often referred to as 'sustainability') there is unlikely to be any conflict between agricultural activities and the provision of ecosystem services, whereas the opposite can be the case.

Much of the emphasis by economists on the interface between agriculture and the environment has been on decision making by individual economic agents on the use of natural resources. This emphasis reflects the focus on individual well-being as the building block of social welfare, and the role of individual decisions in determining agri-environmental outcomes. The supply of goods is conventionally viewed to be determined by decisions made by economic agents (e.g., farmers or ranchers) whose aim is profit maximization. The broader objective of utility maximization has been employed primarily to deal with risk and uncertainty, that is, where there is a difference between expected profit and expected utility

because individuals are not indifferent to risk. It is possible to conceive of agents maximizing a more general utility function that includes a broad range of noneconomic objectives, but a simpler approach involving profit or the expected utility of profit captures the essence of economic decision making and lends itself to determining optimal usage of inputs and outputs (Becker, 1976).

A basic concept in economics is that under appropriate conditions, competitive markets will determine prices for resources, goods, and services that reflect their scarcity and will generate an allocation of resources that is Pareto efficient. Economics also shows that there are many possible Pareto-efficient allocations that could be attained by markets. These would differ in the mix of goods and their distribution among consumers. Ranking alternative Pareto-efficient allocations is equivalent to ranking alternative distributions of income across individuals and generations. Specifically, resource allocation in competitive markets (or indeed under any system for resource allocation) will result in a particular distribution of economic welfare.

A fundamental question in economics is that when does a change in resource allocation improve social welfare. Such a change may involve moving from a resource allocation that is Pareto inefficient to one that is Pareto efficient, or moving from one Pareto-efficient allocation to another. In economics, the assumption is made that a change in resource allocation that increases the welfare of one or more individuals is socially desirable. This is called a Pareto improvement. In such a case, the move would have positive benefits but no costs. No Pareto improvements are possible when an economy is Pareto efficient. Changes in resource allocation that improve the well-being of some but harm others are not Pareto improvements, but may lead to Pareto-efficient allocations. If those who gain could compensate those who lose while leaving both better off, then all could potentially be made better off by the change in resource allocation. In this case, the reallocation is a potential Pareto improvement and would pass a benefit–cost test in determining if the allocation improves economic efficiency. However, judging whether a reallocation that improves the well-being of some while harming others is socially beneficial requires ethical criteria regarding the distribution of income that are outside the realm of economics. Such criteria can be used to define 'social welfare functions' that attach differing weights to the welfare of individuals. This approach has been used, for example, to examine policy choices and their implications for resource allocation in agriculture, where in many countries the welfare of farmers tends to be weighted more highly by policymakers than that of consumers and taxpayers. Defining social welfare functions is challenging and controversial as it is heavily dependent on what value judgments are used to determine whether the welfare of one or some group of individuals is to be weighted more highly than some other individual or group.

A large number of assumptions are involved in applying economic theory to reach the conclusion that a competitive market economy is Pareto efficient. These include access to full or 'perfect' information in making allocation decisions; the existence of well-defined property rights that govern the use of resources, the existence of a sufficient number of buyers and sellers of homogenous goods produced under constant or decreasing returns to scale without barriers to entry and exit in order to preserve competition and prevent monopolization of markets; the existence of perfect factor mobility and absence of transactions costs so that the allocation of resources can respond efficiently to consumptive needs; and an absence of policy-generated distortions. The impact of relaxing these assumptions (e.g., the presence of imperfect competition) on resource allocation and economic welfare has been a major focus of study in economics, as this may provide a justification for corrective action on the part of governments. Despite this, the central tenet remains that the operation of markets in determining what will be produced and consumed is likely to lead to an allocation from which there are no possible win-win alternatives. If the underlying distribution of income is considered fair, then markets can be said to have achieved the highest level of economic welfare for society.

Externalities, Public Goods, and Market Failure

The recognition that private decision making in competitive markets might not lead to a socially optimal allocation of resources dates back to the early part of the twentieth century. The British economist Arthur C. Pigou (1932) is credited with introducing the concept of externalities, whose existence is central to the environmental dimension of agricultural activities. Externalities are sometimes said to result from institutional failure in that they reflect missing markets that result in missing prices. The solution proposed by Pigou was to impose a tax on a negative externality-causing activity and to provide a subsidy for an activity that generates a positive externality. These Pigouvian taxes and subsidies 'internalize' external costs and benefits, that is, ensure that they are taken into account in the decisions of individuals that determine resource allocation. It has also been shown that under certain conditions the use of subsidies and taxes on inputs can achieve equivalent results (Peterson *et al.*, 2002). This is particularly relevant for agriculture as many of its externalities (e.g., pollution resulting from the application of fertilizer to land or agriculture's contribution to maintaining wildlife habitat) are associated with land management practices and the use of inputs and externality outputs may be difficult to observe or measure. Taxes and subsidies are not the only approach that can be used to deal with externalities; measures that establish property rights can also address the issue, as discussed further below following a brief elaboration on the nature of externalities.

A related concept to a positive externality is that of a public good, whose consumption is indivisible or nonrival. It is difficult to charge a price for a public good because it is difficult to exclude individuals from consuming it (because it is nonexclusive). This means that there will be no economic incentive for individuals to supply such goods. Public and quasi-public goods may be provided by virtue of jointness in production with private goods. This is particularly relevant to agriculture, where the use of land in farming may provide both agricultural commodities and ecosystem services. A key issue in this case is whether the economic incentive to produce the private good (food and agricultural products) also leads to a sufficient supply of associated public or quasi-public goods.

Table 1 A taxonomy of some goods associated with land use

	Exclusive	*Nonexclusive*
Rival	Pure private goods: Food and agricultural products	Quasi-public goods: Open access grazing
Nonrival	Quasi-public goods: National parks	Pure public goods: Landscape amenities

Table 1 provides examples of various types of goods that are associated with land use with respect to the two key dimensions: whether they are rival or nonrival and whether they are exclusive or nonexclusive.

Although taxes and subsidies can be used to promote the provision of public and quasi-public goods, this can also be pursued through the creation of property rights – rights of use or ownership that permit a charge to be levied for usage or consumption (Coase, 1960). For example, the goods that are excludable but nonrival (e.g., performances in theaters and cable television) can be provided by markets if the costs of production plus exclusion are less than the revenues that can be obtained from supplying them – these are called club goods (Buchanan, 1965). Another example is the use of markets to allocate polluting emissions among alternative sources. In this case, governments create property rights to pollute, but restrict the amount of pollution that is allowed (Crocker, 1966; Dales, 1968; Goulder, 2013).

The absence of property rights or imperfections in property rights plays a key role in the overexploitation of common-pool resources, such as common grazing land or timber from public forests. For markets to allocate goods efficiently, property rights must be exclusive, enforceable, and transferable. The absence of enforceable exclusive property rights results in the classic problem of open access. The private cost of the exploitation of open access resources by an individual is less than the social cost, resulting in overexploitation (Hardin, 1968). The issue of whether and under what conditions individual members of a collectivity, acting in a self-interested manner will supply public or quasi-public goods has been addressed (e.g., Olson, 1971; Janssen, 2013). There has also been empirical work on this issue. Ostrom (1990), for example, examined how communities manage communal resources, such as land, and identified several key factors conducive to successful collective action:

1. The resource in question must have definable boundaries.
2. There must be a perceived threat to the resource for which it is difficult to find substitutes.
3. There is a community – a small and stable population with a dense social network and social norms that promote conservation.
4. Community-based rules and procedures exist that provide incentives for responsible use of the resource/penalties for overuse.

Intertemporal Allocation

As noted in the Sections Efficiency in Markets and Externalities, Public Goods, and Market Failure, resource management is an important question in economics with attention focusing on the efficient allocation of resources across time and space, the implications of alternative regimes for property rights, market structures, the role of information, and the design of market or nonmarket institutions to correct for market failure. In terms of individual decision making attention focuses on the economic returns from the use of natural resources.

Resources can be classified as expendable, renewable, or depletable depending on the period of adjustment involved in their use (Carlson *et al.*, 1993):

1. Expendable – adjust rapidly such that use in one time period has little effect on availability in subsequent periods.
2. Renewable – self-renewing within a period relevant to economic decision making.
3. Depletable – adjust so slowly that one can meaningfully treat them as being available only once within a period relevant to economic decision making.

Land is a complex resource in that it can yield all three types of resource:

1. Expendable – agricultural crops.
2. Renewable – forests, forest products and fuelwood, livestock and wild animals, flowers and insects, groundwater, and animal populations (providing that use does not cause irreversible changes in potential availability).
3. Nonrenewable – endangered species, top soil, virgin wilderness, and water in some aquifers.

The analysis of decision making for expendable resources has focused on levels of input use in a single production period or over a limited number of periods to maximize profits, for example, how much land to devote to wheat or oilseed production and what quantities of inputs, such as fertilizer and labor to apply to that land.

The focus on depletable and renewable resources has been on the optimal rate of depletion over time. The management problem is typically framed in terms of the maximization of the net present value of the flow of benefits from consumption less the costs of extraction or harvesting over a future time horizon, subject to the dynamics of resource (how the stock evolves over time), initial stock size, a target for the end of the planning horizon (or a limit in the case of an infinite time horizon), a measure of time preference (the discount rate), and other relevant market, price, and technology constraints. In the case of depletable resources, current use irreversibly reduces the resource stock available for future use. In the case of renewable resources, natural processes can result in stock growth for future consumption. In both cases, economically optimal use is achieved when the marginal cost of extraction or harvesting plus the current opportunity cost of extracting the resource (the value foregone by not exploiting the resource) equals the marginal value of consumption (Hanley *et al.*, 2002). The magnitude of the interest rate (the discount rate applied to future economic benefits from the use of the resource) will affect the rate of depletion: a higher rate will accelerate depletion and a lower rate will reduce it. The key role played by the discount rate in the determination of optimal rates of resource depletion has generated much discussion in economics and this is analyzed further below in this section. Economic

efficiency is obtained when the marginal private benefits under a particular time path are equal to the marginal cost of harvesting plus the opportunity cost of the resource.

A key feature that distinguishes renewable from nonrenewable resources is the capacity of renewable resources to be managed to steady states, characterized by a situation in which the resource inventory does not change over time. The steady state that supports the maximum physical use of the resource (harvest) that can be sustained indefinitely is the maximum sustainable yield. However, the economically optimal harvest rate, which takes into account costs associated with the use of a resource, will generally be lower than the maximum physically sustainable yield. The economic optimum depends on interest rates. Increasing extraction costs will tend to lower the current use of the resource, whereas higher interest rates (implying a higher discount rate on future consumption) will tend to increase current usage. The management of the resource over time will also depend on the resource-growth function, that is, how resource inventory is affected by the rate of current usage. In the case of soils, for example, an expansion of productive capacity may be needed to reach a steady state equilibrium if the existing productive capacity of the soil is below the economic optimum. However, as the present value of future opportunity costs associated with current extraction is close to zero if the discount rate is sufficiently high this may dictate exhausting the soil resource (McConnell, 1983; Shortle and Miranowski, 1987). In other words, the fact that soil is a renewable resource does not necessarily imply that it is economically optimal to sustain it (see Section Soil Quality).

The management of natural resources, such as land, may have irreversible outcomes, for example, the conversion of land into alternative uses can create irreversible changes to ecosystems or biodiversity. If, for example, the possibility of increased consumer preferences for the nonagricultural goods associated with land (e.g., ecosystem services) is not taken into account, then current 'overuse' of the land resource may result. This may be viewed as another example of market failure, but one which is more speculative and difficult to address than that resulting from identifiable unpriced externalities, such as the costs imposed on others by soil erosion.

The difference between physical and economic sustainability is clearly an important issue and the key role of the discount rate in determining the optimal economic use of both renewable and nonrenewable resources should be underlined. The use of a discount rate reflects the assumption that individuals place a lower value on events that occur in the future (including consumption) relative to current events. Higher discount rates reduce the present value of future consumption, and dictate that the benefits of using a resource will be realized sooner. The importance of the discount rate in determining the optimal rate of depletion (or conservation) of natural resources inevitably leads to considerations of whether the private discount rate is equivalent to the social discount rate – the rate at which society would discount the future stream of benefits from using a resource (Baumol, 1968). This raises a complex set of issues, not least of which is how the socially optimal rate should be determined. The issue of discounting is particularly controversial in the context of the debate about intergenerational equity, for example, whether it is 'fair' for one generation to use resources so that they are unavailable to future generations or to behave in the management of renewable resources that could reduce the economic welfare of future generations. The importance of discount rates in sustainability analysis is currently most prominently on display in analyses of optimal policies for addressing climate change (Nordhaus, 2007).

Nonmarket Valuation

A central assumption in economics is that individuals are able to place a value on the goods and services they consume. Consumers maximize utility by choosing among such goods and services based on such valuations. When confronted with a set of prices they determine the amounts that they wish to purchase based on tastes, preferences and their income. It is possible to tradeoff quantities of various goods against one another in determining consumption choices and those choices reveal willingness to pay (WTP) for particular goods and services. The problem with many environmental goods is that valuation is not possible because of missing markets. Various approaches have been used to infer values (implicit prices) of unpriced environmental goods and services (Hanley and Barbier, 2009). The most popular approach has been contingent valuation (CV). Other approaches make use of goods that are substitutes for or complements to environmental goods, for example, the use of travel costs to estimate the value placed by users on recreational sites or hedonic pricing – how environmental quality affects local property prices. In this approach, surveys or experiments involving hypothetical choices are used to infer the value that individuals place on environmental goods. An advantage of the approach is that not only can it be used to determine values for goods and services that individuals may actually consume (e.g., clean water or recreational services), but it can also be used to determine values for the nonuse of environmental goods, i.e., existence values – the value that results from knowing that a resource exists (e.g., wilderness areas and endangered species) even though that resource confers no direct consumption benefits.

Stated preference (e.g., CV and choice experiments involving groups of individuals) and revealed preference (e.g., travel cost and hedonic price) valuation methods seek to elicit values through estimates of the WTP to obtain a positive externality, public, quasi-public, or to avoid an externality (e.g., pollution). An alternative approach is to estimate willingness to accept (WTA), that is, the amount an individual would be prepared to receive if prevented from obtaining a good or to accept something undesirable (Venkatachalam, 2004). WTP estimation has been more widely applied than WTA as the former is constrained by an individual's wealth. WTA estimates for some goods may be high in comparison to WTP estimates because of the lack of this constraint.

There is an ongoing debate on CV methodology, particularly on how to improve the accuracy and reliability of estimates obtained. Some economists are highly critical of the ability to derive meaningful values for intangible goods and services through the CV approach, and, in particular, to derive values that reflect prices that consumers would actually be prepared to pay if they were faced with purchasing these goods

and services in a market (Diamond and Hausman, 1994; Hausman, 2012; Horowitz and McConnell, 2002).

Both WTP and WTA assume that it is possible for individuals to value unpriced attributes, whereas this may not always be possible (or acceptable). One class of goods that would fall under the nonacceptability heading is moral goods – goods that are associated with moral values, that is, whose provision is viewed to be morally necessary and not necessarily subject to an economic calculus. Although he does not use the term, the concept of moral goods is implicit in the arguments made by Spash (1997) that moral or ethical values make it difficult to value some environmental goods. As with distributional judgments and judgments of what constitutes fairness or equity, this area is fraught with difficulty as moral values can differ among individuals and this is not generally addressed in economics. To the extent that moral goods can be addressed, economists would probably look for mechanisms to ensure a generally accepted level of provision (e.g., minimum quantity that would be generally accepted by society). It is possible for preferences for higher levels of provision to be reflected through the pricing mechanism. An example here would be water quality. Most individuals would accept that water quality should be such that consumption does not provide a significant risk to health (e.g., through high levels of dangerous contaminants). Beyond that, however, it may well be possible to examine the benefits and costs of supplying water that satisfies higher standards of quality in terms of chemical composition, taste, or other criteria.

Information and Information Asymmetry

As noted in the Section Externalities, Public Goods and Market Failure, taxes and subsidies can be used to address externalities and the provision of public goods. Taxes are rarely used in this context in agriculture for both technical and political reasons. There has been a tendency in wealthy countries to provide incentive payments (subsidies) through agri-environmental programs to pursue environmental objectives in agriculture. Determining the size of payments that will achieve a desired outcome is a problem as a farmer (the agent) will generally possess more information than a policymaker (the principal) about the effect of her/his economic activities and the costs of supplying environmental goods. Such asymmetric information is the central characteristic of the principal–agent problem that has received a lot of attention from economists in analyzing the design of agri-environmental programs (e.g., Shortle and Dunn, 1986; Wu and Babcock, 1996). The problem can result in a number of issues including adverse selection – the tendency for those who are most likely to supply the desired environmental services in any case to want to participate in a program, rather than the poor environmental performers who are the prime targets. Fixed payments may pose particular problems as they may encourage an undersupply of environmental services from producers in areas where it costs more to supply these and an oversupply in other areas. The targeting of payments may be more efficient if a mechanism is used through which producers reveal their costs of provision (or WTA) through an auction process (such as that used in the US Conservation Reserve Program).

The response of producers to incentives under agri-environmental programs is the focus of considerable research (Uthes and Matzdorf, 2013). Some of the issues addressed are the implications of risk and uncertainty for program compliance and environmental outcomes, the role of transactions costs, the amount of monitoring size, and structure of penalties to ensure compliance. The literature in this area suggests that there is a complex interaction between these factors in determining the response of producers to incentives provided through agri-environmental programs.

Agri-Environmental Externalities, Natural Resources, and Public Policy

Table 2 lists some externalities associated with agricultural production, characterizes their economic impacts, and suggests methods that can be used to estimate their economic importance. This list should be considered illustrative. This section elaborates the economic features of selected elements of this list and policy approaches that are used to address these elements.

Agri-Environmental Policies and Programs

In the context of land use and agriculture the issue of missing markets has been central to environmental outcomes from agriculture's use of natural resources. The issue has often been addressed through mechanisms that try to ensure the provision of environmental goods (such as wildlife habitat) and reduce the provision of environmental bads (such as pollution). Some of the very earliest agri-environmental programs were directed toward the control of soil erosion, such as the Dust Bowl in the United States.

The provision of environmental goods in agriculture has been addressed through the following mechanisms:

1. The specification of management practices to be followed as a condition for receiving payments that have non-environmental objectives, primarily income support (cross-compliance).
2. The use of regulations, particularly for the use of animal waste, applied to large livestock operations in order to reduce pollution (regulation).
3. The use of incentive payments to induce producers voluntarily to implement particular environmental practices that reduce negative externalities/increase positive externalities from agricultural production; to enhance the supply of public/quasi-public goods; or to induce producers to convert environmentally sensitive working lands from productive uses into permanent vegetative covers, or to prevent the conversion of environmentally sensitive lands into productive use (agri-environmental programs).

Mechanisms 1 and 3 are based on the use of economic incentives to encourage farmers to adopt appropriate practices. Mechanism 2 will impose an economic cost on farmers but relies on command and control to achieve environmental aims. Economists argue that, other things being equal, if incentive payments are used they should be targeted to specific

Table 2 Inventory of agricultural externalities

Externality	*Environmental impact*	*Economic impacts*	*Valuation method(s)*
Increased stormwater runoff	More variable stream flows	Increased flood damage	Hedonic analysis of property values
	Increased stream erosion	Decreased base flows to support aquatic biota	Cost of insurance and remediation
		Loss of productive soils and acreage	Lost recreational values via travel cost method
			Value of lost agricultural production
Sediment and salts in runoff or irrigation return flows	Clog streams and drainage channels	Higher channel and reservoir maintenance costs	Added costs of maintenance, water treatment, and flood damages
		Higher water treatment costs	
		Increased flood damage	
	Increased turbidity	Altered biotic communities	Species valuation via stated preference methods
		Diminished recreational values	Lost recreational values via travel cost method
		Reduced water amenities	Hedonic property value analysis of changed amenities
	Salinization and accumulation of toxic compounds in water	Diminished usefulness of water	Increased costs of treatment or substitute supplies
		Death, deformity, and reproductive abnormalities in wild and domesticated animals	Lost recreation values via travel cost method
		Human health impairments	Lost wildlife values via stated preference methods
			Human health values via opportunity cost valuation
Pesticides	Chemicals present in drinking water, food, and fish tissue	Increased risks to health of humans and fish/wildlife	Opportunity cost of health impairments
	Disturbances to aquatic ecosystems	Less-productive ecosystems	Lost recreational values via travel cost method
			Nonconsumptive wildlife losses via stated preference methods
Livestock wastes	Increased pathogens	Increased human health risks	Opportunity cost of health impairments
	Other effects similar to fertilizers	Other effects similar to fertilizers	Hedonic property value analysis
	Odors	Decreased amenity and property values	
Climate/atmospheric modification	Change in solar gain	Changes in heating/cooling costs	Increased heating/cooling costs
	Release or sequestration of greenhouse gases	Changes in long-term climate warming	Opportunity cost of respiratory impairment
	Dust generation	Increased respiratory impairment	Increased cost of infrastructure maintenance
	Changes in wind patterns	Increased fouling of infrastructure	
Low-diversity vegetation or animal communities	Reduced diversity and resiliency of regional ecosystems	Reduced natural pollination services	Opportunity cost of substitute inputs
		Crop damages and increased accidents due to wildlife population imbalances	Market value of crop and accidental losses
		Lost amenity and existence values	Insurance premiums for added exposure to losses
			Stated preference values or voluntary contributions for amenity and species existence
Accelerated genetic evolution	Disease generation	Animal and human morbidity and mortality	Opportunity cost of lost economic activity and mitigation efforts

Source: Adapted from Table 1 of Braden, J.B., Shortle, J.S., 2013. Agricultural sources of water pollution. In: Shogren, J. (Ed.), Encyclopedia of Energy, Natural Resource and Environmental Economics. Oxford: Elsevier Science, pp. 81–85.

environmental objectives, rather than bundled with other objectives. The reason is that producers can more easily make decisions on whether to supply environmental goods based on the costs of doing so when the reward is clearly linked to the desired outcome. Another reason is that the size of a payment that has other objectives (e.g., income support) may have little relationship to the potential environmental benefit that a recipient could generate. An old and well-established principle is that it is efficient to have at least as many instruments as objectives in economic policy (Tinbergen, 1956). This would dictate that there should be at least one instrument targeted to the income objective and another targeted to the environmental objective.

With the exception of mechanism 2 there has been a marked reluctance by policymakers in most countries to use taxes to address negative externalities in agriculture. Even if those who receive subsidies respond in the desired manner by adjusting their production practices or level of output, subsidies may be less efficient than taxes in reducing negative externalities because they can encourage polluters to enter the industry or existing high-polluting firms to continue to operate. In contrast, taxes would discourage entry and would not impede structural change that could lead to the exit of more polluting firms (Baumol and Oates, 1988).

Water Pollution and the Nonpoint Source Problem

Arguably, the most significant externality associated with agriculture in North America and Europe, and of great importance elsewhere, is water pollution. This section draws extensively on Shortle and Braden (2013). Negative water quality impacts from agriculture are a pervasive issue in regions with intensive crop and livestock production. Fertilizer, animal manures, and pesticides applied to agricultural land, sediment from eroded soils, and salts and heavy metals leached from soils are carried by irrigation return flows and storm runoff into surface waters causing a range of environmental damage. Pollutants seep into groundwaters damaging water supplies and move as base flow to pollute surface waters. Some pollutants move as gases from farm fields and manure storage facilities into the atmosphere but become water pollutants with atmospheric deposition. These complex and diffuse flows are referred to as nonpoint source pollution. Discharges from pipes or discharges into surface waters from barnyards and feedlots are classified as point source pollution. Pollution problems vary with types of agriculture and impacted water systems. Of widespread significance are damage from nutrient (nitrogen and phosphorous) pollution of fresh, estuarine, and coastal waters. Although nutrients are discharged into waters by industrial and municipal sources, and by atmospheric deposition of air pollutants, agriculture is often a major source. Nutrient pollution damages aquatic ecosystem and harms commercial and recreational activities (e.g., fisheries) dependent on them. Significant examples of nutrient pollution problems are found in the Chesapeake Bay, the Gulf of Mexico, and the Baltic Sea.

The dichotomy between point and nonpoint source pollution is extremely important for policy design. Emissions from point sources of pollution can generally be metered and regulated more or less directly. This allows the use of the emission-based policy instruments generally recommended by economists for the efficient control of polluting emissions from point sources: emission taxes and tradable discharge permits. Where possible, countries use effluent standards or technology standards for point sources, including agricultural point sources if these are regulated. The regulation of nonpoint pollution, which is by far the most important type of pollution in agriculture, poses problems because diffuse pathways make metering emissions difficult, and because nonpoint emissions are driven by uncontrollable natural processes, weather being the most important. In consequence, economists' preferred base for regulation, polluting emissions, is not available. The economic analysis of nonpoint pollution control is, therefore, concerned with the choice of observable pollution abatement activities or other outcomes to measure and manage nonpoint pollution (the compliance base), as well as choice of incentive mechanisms, and design details within those choices (Braden and Segerson, 1993; Shortle and Horan, 2001). As weather events can influence the timing and volume of emissions that reach a water body, violations of an ambient environmental goal may occur because of forces beyond human control. Nonpoint pollution management is, therefore, best framed as attempting to achieve a desired probability distribution of ambient conditions rather than a specific deterministic pollution target. For example, it might be desirable to hold concentrations of Nitrogen (N) in receiving waters below 10 mg l^{-1} for 90% of the time.

As a result of stochasticity and unobservability, efficiency in the control of nonpoint pollutants is not readily characterized by conventional rules about equalizing marginal costs of emission abatement. Instead, efficiency must be characterized in terms of cost minimization in the management 'levers' or 'observables' that are actually used. An obvious starting point is to look 'upstream' at observable factors that influence emissions. Examples in agriculture are fertilizer, manure, and pesticide applications; tillage practices; and installation of vegetative filters and buffers. An efficient nonpoint pollution control allocation would be described as the set of input choices by all nonpoint sources that minimizes the social costs of achieving a particular ambient pollution target. In principle, this allocation can be achieved in various ways. One would be through a set of input standards that command polluters to select the efficient allocation. Given the spatial variations in site characteristics, weather, and other factors that would determine optimal input structure for specific locations, the efficient input structure, and thus input standards, would vary from polluter to polluter. This heterogeneity would make such standards administratively complex and costly as inputs and input-specific rules and procedures would generally be required to govern many choices by many polluters. It would also incentivize local black markets in regulated inputs and legal challenges based on perceptions of unequal treatment or scientific uncertainty. Furthermore, the design would be informationally and computationally costly.

Another mechanism for achieving the efficient outcome is through taxes on inputs. If the ambient pollution level were simply equal to the sum of polluting emissions, and an emissions model predicted emissions without error, then an

efficient input tax structure would be one with rates that are proportional to the marginal impact of each input on emissions. These rates would be positive for inputs that increase pollution (e.g., fertilizer) but negative for inputs or activities that reduce pollution (e.g., conversion of streamside cropland to a riparian buffer). Tax rates would vary across inputs (nitrogen vs. phosphorus fertilizers) and polluter types (e.g., by type of crop and erodibility of soil) according to variations in marginal impact by input and pollutant. This is a potentially complex rate structure. With uncertainty about the impact of an input on emissions, the rate structure would become even more complex, affected by multiple moments of the probability distribution of impacts as well as possibly by geographic location, and therefore harder to quantify and defend. More plausible input-based instruments (taxes, standards, or a combination of the two) would involve a reduced set of regulated inputs; those that are easily observed and particularly influential. Limited and predetermined differential treatment of polluters through tax rates or input standards would reduce information costs and help minimize perceptions of inequity. However, these limitations would impose an efficiency loss through increased cost of pollution control, but with reductions in the transaction costs from design, implementation, and administration.

Input-based instruments are common in nonpoint pollution control (Shortle and Horan, 2013). In agriculture, examples include regulations on the use of pesticides and on waste handling at large confined animal enterprises, although the latter are essentially point sources of pollution. Input taxes are used to a limited extent. Several European countries levy environment-based taxes on pesticides and fertilizers. As noted earlier, the most common approach in agriculture is the provision of subsidies for voluntary adoption of pollution-reducing practices. Research has shown conventional subsidies to be ineffective in some cases and inefficient in general, because they encourage more farming, even if the pollution from each farm is reduced (Shortle *et al.*, 2012).

If a pollution model is available that specifies the relationship between inputs and output, it could be used to apply a policy instrument linked to an individual polluter's contribution to ambient pollution. The switch from inputs to indicators of environmental performance is appealing because it would shift the regulatory focus from the means to the ends. It might also offer possibilities for simplification. Despite this, there are a few examples of the use of such an approach. Belgium and the Czech Republic tax estimated ammonia emissions from large-scale animal operations. The Netherlands has experimented with taxing the use of nutrients in excess of the capacity of soils and crops to recycle these. Interest in performance-based instruments is prompted in part by research showing that efficiency and effectiveness in nonpoint pollution control is generally served better by targeting the outcomes of producers' choices than the choices themselves.

Owing to the inherent difficulties in regulating nonpoint sources of pollution, there has been heavy reliance on voluntary participation induced by education, subsidies, and other forms of positive incentives. Within this domain, market-based voluntary trading is an area of significant interest and innovation, particularly for nutrient pollution. Experiments with nutrient trading began in the United States in the early 1980s. They have primarily involved efforts to reduce nutrient emissions from nonpoint sources as an alternative to costly measures to reduce nutrient discharges from regulated sewage treatment plants. The results of early experiments were disappointing, with few trades taking place, but interest in trading has grown nonetheless. Trading programs to control nutrient pollution from point and nonpoint sources have been developed in Canada, the United States, and New Zealand and have attracted interest elsewhere (Shortle, 2013).

Markets for trading nonpoint pollutants developed to date in the United States and Canada are not the cap-and-trade permit markets of textbooks. Rather, these markets foster trade in emissions reduction credits earned by polluters when they reduce emissions below a baseline. The markets can be described as 'partially capped' because point source polluters face explicit discharge limits, whereas nonpoint polluters are not regulated but participate voluntarily as suppliers of credits. The one effort to date to create a true cap-and-trade market for nonpoint pollution is aimed at the reduction of nitrogen pollution of Lake Taupo in New Zealand.

The performance of pollution markets is powerfully affected by details of market design. An essential feature of markets for nonpoint pollutants developed to date is that they trade estimated or modeled reductions in nonpoint emissions in exchange for measured point source emissions. Economic research on the design of markets for estimated nonpoint emissions has focused largely on the appropriate trade ratio between monitored point emissions and those estimated for nonpoint sources. The point–nonpoint trade ratio is commonly defined as the number of nonpoint permits (or credits) that a point source must purchase to offset a unit of its own emissions. Trading programs developed to date almost always set this ratio in excess of one on the grounds that uncertainty in nonpoint emissions requires a margin of safety to assure that a nonpoint reduction will, in fact, offset point source emissions. Although this view is clearly appealing to real-world trading program designers, economic research has shown that this approach can increase rather than reduce environmental risk (Horan, 2001). Essentially, trade ratios in excess of one penalize substitution of nonpoint pollution reductions for point source pollution reductions. This penalty will bias pollution control toward a reliance on point sources, the result of which will be to leave the risky source, nonpoint pollution, relatively uncontrolled.

Another approach that focuses on environmental outcomes is to create economic incentives tied to actual water quality conditions. A number of variants of ambient-based incentive schemes have been proposed, including taxes, tournaments, and threat mechanisms intended to induce collective action amongst polluters (Segerson, 1988; Govindasamy *et al.*, 1994). However, this approach poses significant cognitive challenges for polluters. An efficient outcome would require polluters to be able to determine the relationship between their individual choices and ambient pollution levels and to understand the aggregate impacts of others on environmental outcomes. It requires sophisticated decision-making skills in uncertain situations. The behavioral economics literature indicates that the capacity of an individual to optimize in complex settings is limited. Ambient taxes also require strong assumptions

about polluters' strategic choices. Researchers have explored the issues using experimental economics laboratories and found that ambient taxes can perform well with respect to efficiency in laboratory settings, contingent on certain specific design features, when subjects are not allowed to communicate (Suter *et al.*, 2008). Communication between laboratory participants leads to group profit maximization and inefficient overabatement.

There is no example of the use of ambient taxes in their pure form. However, collective incentives have been addressed in other forms. In 1994, the US state of Florida enacted basinwide incentives as part of a suite of programs to reduce phosphorus pollution in the Everglades. The programs include an agricultural privilege tax imposed on cropland to fund pollution control initiatives. Reductions in phosphorus discharges below a 25% goal for the basin would result in collective credits (i.e., reductions in the tax rate) against the privilege tax. The program also provides credits to individual farmers based on farm-specific performance.

This discussion indicates that a variety of approaches can and have been used to address water pollution from agriculture. However, the problem remains pervasive and is a top priority of environmental policymakers in many countries. The lack of progress can be blamed, in part, on the challenges posed by the nonpoint problem and the transactions costs that governments would likely incur in implementing more effective approaches to reducing pollution. The political economy of agricultural regulation (the political challenge of trying to regulate agriculture) is also a factor because it often leads policymakers to rely on ineffective and inefficient voluntary compliance approaches.

Biodiversity

Agricultural development has historically been a major cause of reduced biodiversity. Agricultural land is created by converting wetlands, forests, prairies, and other landscapes into agricultural production. Typically, diverse plant and animal communities are replaced by much less diverse assemblages of commercially valuable species. Some of those species may have been engineered to combine traits unknown in nature. When a large fraction of the landscape is dominated by artificial communities, species that would otherwise have prospered can be edged out and replaced by ones better adapted to the new circumstances.

This historical relationship between agriculture and biodiversity suggests a need to protect biodiversity-rich landscapes from agricultural production, and this is in fact important where such landscapes are threatened by agricultural development. However, agricultural lands are essential to remaining species that find habitat in agroecosystems. Some species depend on 'natural' areas within agricultural landscapes, whereas others have adapted to croplands and pasturelands. In consequence, restoration and protection of habitat on agricultural lands is also important for biodiversity conservation. Taking current conditions as a baseline, changes in agricultural land use that restore or improve habitat generate positive externalities, whereas changes that diminish habitat generate negative externalities.

A loss of diversity can be economically significant in several respects (Declerck *et al.*, 2014). Some imperiled species may be economically important, for example, pollinators whose services are essential to some types of crops and predators that constrain deer populations and prevent crop losses and auto accidents. Species are also valued by some people for their mere existence or for viewing, as reflected in the financial contributions to or involvement in preservation causes and the establishment of conservation areas.

A variety of economic methods have been used to value the economic benefits of species diversity. The contributions of diversity to commercial values can be measured by the market value of losses associated with diminished diversity, the insurance premiums paid to hedge against losses or cost of substitutes for lost services, such as rented pollinator colonies. The contribution to amenity and existence values can be measured through stated preference or experimental methods (as discussed in the Section Nonmarket Valuation) or approximated by voluntary contributions to preservation causes including conservation areas.

Strategies for addressing losses of biodiversity are diverse and make selective use of economic instruments. In the United States (Walls and Riddle, 2013), the Endangered Species Act limits the rights of landowners who host species recognized as threatened or in danger of extirpation. These programs create powerful incentives to avoid involvement or to take preemptive actions, such as species elimination, thereby raising the ultimate cost of preservation. Other programs offer payments for ecosystem service provision (Parkhurst, 2013). For example, federal agricultural programs have included subsidies for converting cultivated land into vegetative cover and for the restoration of wetlands. Popular in the 1990s and early 2000s, the impact of these programs has been reduced by strong demand and high prices for agricultural products as well as reduced government funding. Subsidies are also known to create inefficiency by inducing more agricultural activity overall, even if some of its resources are diverted toward environmental improvements. Fueled by tax benefits available to contributors, in the United States, private organizations and government at many levels have worked together to purchase or place easements on land for conservation reserves (Parker and Thurman, 2013). In Australia, the states of Victoria and New South Wales have developed markets and banks for biodiversity conservation credits (Carroll *et al.*, 2009). However, many conservation investments are made opportunistically with little coordination to maximize their overall contributions to species diversity. As future conditions are uncertain and biodiversity depends on complex interactions between species, researchers have proposed the use of modern portfolio theory (Markowitz, 1954) to determine portfolios of species (Figge, 2004) and reserves (Ando and Mallory, 2012) that optimally balance risks and returns.

In the United States, some states restrict the conversion of land to other uses (e.g., urban development) to limit losses of unusually rich ecological resources, such as wetlands (National Research Council, 2001). The restrictions are coupled with markets where developers can trade 'credits' for ecological functions (Mills, 1980). Developers who create or enhance wetlands and are willing to accept permanent conservation easements receive credits that can be sold to others who seek

to eliminate or degrade wetlands elsewhere. The credits can be deposited in 'mitigation banks' and sold later. In many European countries, the conversion of land to other uses is controlled through planning laws.

Air Quality and Climate

Agricultural activities can result in a variety of air pollutants. Wind erosion and field operations can add particulate matter to the atmosphere. Winds can cause sprayed pesticides to drift. Livestock production releases hydrogen sulfide, ammonia, methane, volatile organic compounds, and odors. Particulates and nitrogen oxides are emitted from diesel- and gas-powered equipment, and from fields cleared of unwanted vegetative material by burning. These pollutants may affect human health and ecosystems, reduce visibility, and create nuisances. In general, however, agriculture is not considered to be a major source of ambient air pollution compared with major industrial, transportation, and power generation sources, and is little regulated at this time. Air emissions from agriculture often share the characteristics of water emissions (diffuse and stochastic), with the result that regulation would pose similar challenges. Ozone, nitrogen oxides, sulfur dioxides, and other pollutants generated by nonagricultural activity can adversely affect various types of crops and the returns from agricultural production.

Growing concern about human-induced climate change, which is driven largely by increased release of heat-trapping greenhouse gases (GHGs), has begun to focus more attention on agriculture's contribution to what can broadly be defined as air quality. Agriculture is not the largest source of GHG emissions – the combustion of fossil fuels for power generation, industry, and transportation are the major sources and are primary targets of regulatory initiatives. However, when measured relative to its share of gross domestic product (GDP), agriculture is an emissions-intensive sector. Although it accounts for only 6% of global GDP agriculture is estimated to account directly for 14% of total anthropomorphic GHG emissions, primarily in the form of carbon dioxide, methane, and nitrous oxide (IPCC, 2007). If emissions resulting from the conversion of land from forests to agriculture are included the percentage is higher. The food system as a whole is estimated to be responsible for 19–29% global GHG emissions with agricultural production, including indirect emissions associated with land-cover change, contributing 80–86% of the total (Vermeulen *et al.*, 2012). Agriculture is an unusual sector in that it also extracts carbon from the atmosphere in the production of biomass and can sequester this carbon for periods of time. Climate change resulting from increasing concentration of GHGs will also affect the sector. The concentration of carbon dioxide in the atmosphere could increase crop productivity. Production could be affected spatially, either positively or negatively, by climate change through increases in average temperatures, a higher incidence of temperature extremes, changes in the length of growing seasons, and changes in rainfall patterns.

Economic research on climate change policy is dominated by a debate between price-based and quantity-based instruments for reducing GHG emissions. Price-based policies would impose a tax on GHG emissions. By increasing the cost of those emissions, it would induce consumers and producers to substitute less GHG-intensive products and methods of production. For example, the meat of high methane-generating animals (such as cattle and sheep) and N_2O-producing nitrogen fertilizers would both become relatively more expensive. Consumers would be encouraged to substitute away from red meat and farmers would be encouraged to use less nitrogen. Quantity-based instruments, however, seek to impose limits on physical emissions. A common proposal is to allocate tradable emission allowances (permits) to emitters. Overall quotas would be set on GHG emissions and each emitter would be required to possess allowances sufficient to cover their emissions. The ability to trade allowances would provide flexibility, and the existence of the quota would generate a price. The initial allocation is a major issue. Theoretically, if initial allocations are sold to emitters, the equilibrium allocation and price that would emerge in the market should equal the allocation that would be produced by an emissions tax equal to the equilibrium price. This is a general finding for all pollution allowance markets – GHGs or otherwise. If permits are given away free of charge, however, they would act like a subsidy, encouraging more polluting activities than an equivalent tax, although the market would still produce an efficient short-run allocation of abatement effort. Free permit allocation also creates a windfall and competitive advantage for existing emitters relative to new firms who would like to enter the market. Of course, emitters argue strenuously for free allocations and governments are reluctant to create a competitive disadvantage for their emitters relative to those in other countries. Environmental groups argue that polluters should pay for the use of scarce climate resources.

A market for GHG emission allowances would allow the possibility of earning credits for efforts that remove carbon from the atmosphere. Planting trees, for example, would tie up carbon while releasing oxygen. Agricultural interests groups have argued that reducing tillage, growing perennial crops, and setting aside land for conservation are positive contributions of this type by retaining or returning carbon to the soil. Climate change is the result of GHG accumulation over decades, however, this turns out to be a temporary proposition. Over decadal time frames, trees die and degrade, cropland is likely to be tilled periodically, and conserved acreage may be returned to production. GHGs stored in the soil would be released. Only if ultimate releases were reflected in emission allowances would the initial award of credits be efficient. In effect, farmers would be paid a rent for temporarily storing carbon but would have to pay back if and when the stored carbon is released. A second complicating factor is the difficulty of distinguishing storage measures that would be undertaken as a matter of course from those induced by the availability of compensation. Rewarding efforts that would be undertaken anyway is an inefficient use of resources. Finally, both allowances and taxes are vulnerable to nonuniform application. If the United States, for example, taxes GHGs or imposes allowances while a major agricultural competitor, such as Brazil does not, or the two nations act in ways that produce different tax rates or allowance prices, some GHG-generating activity could simply move from one country to the other. This is known as carbon leakage. As global warming is truly a global problem, simply moving emissions around can

be counterproductive, unless it results in a shift of production to more emissions-efficient regions, that is, regions that can generate products with lower emissions per unit of output. However, apart from nations that generate few GHGs but are exposed to huge potential costs, like low-lying islands that will be affected by increases in sea level due to the melting of polar ice, most countries have every incentive to gain relative economic advantage through climate change policies and little incentive to adhere to binding international agreements. Accordingly, coordinated international action on climate change policies has been exceedingly difficult to achieve.

Agricultural Landscape Amenities

The agri-environmental externalities described in the Sections Water Pollution and the Nonpoint Source Problem, Biodiversity, and Air Quality and Climate pertain to the effects of agriculture on the quality of environmental resources. Another important type of ecosystem service associated with agriculture is rural amenities. The conversion of agricultural land into developed uses with urban expansion was long framed as a concern for the loss of agricultural production potential. However, the scope of benefits is now recognized to include the protection of various ecosystem services that are lost or degraded with conversion, and the loss of agricultural landscape amenities (Duke and Aull-Hyde, 2002; Gardner, 1977; Kline and Wichlens, 1996, 1998; Lynch, 2007). Being public goods, landowners can receive no compensation for the provision of amenities or local ecosystem services provided by farm land, possibly resulting in suboptimal supplies without public policy intervention. Concern for farmland preservation has led to state and local policy initiatives across the United States, but especially in the densely populated Northeast. The preservation of farmland and agricultural activities that are judged to be important for the maintenance of landscapes has also been a major policy focus in Europe. Indicative of the demand for such programs in the United States is that they are often the result of referenda in which voters directly choose to create and fund preservation programs. Also indicative of the demand are numerous studies demonstrating that people are willing to pay to protect farmland through various mechanisms (Bergstrom and Ready, 2009). Common tools for farm land protection in the United States include laws to protect agriculture from nuisance law suits (right to farm laws), tax incentives, conservation easements, and purchase of development rights. In Europe, restrictions on development through planning laws and the use of incentive payments through agri-environmental programs have been the principal mechanisms used to preserve landscape amenities.

Soil Quality

With few exceptions, soil is an essential input in agricultural production. To grow crops, soil is combined with water, seeds, fertilizers, and other capital and labor inputs. To some extent, these inputs are substitutable, for example, fertilizer can compensate to some degree for lower inherent productivity of soil. At the extreme, hydroponic production eliminates the need for soil altogether. However, for most agricultural purposes, soil is essential.

Soil is a renewable resource. New soil forms as rock wears down, plant matter degrades, and wind and water move soil particles from one place to another, but these processes take millennia to unfold. Meanwhile, by exposing soil to sun, wind, and rainfall, farming accelerates soil degradation. From the perspective of an individual economic decision maker, soil may, therefore, be viewed as an exhaustible resource, because of the length of time taken for renewal. An important long-run economic issue for agriculture (and for society as a whole) is whether net soil degradation imperils future economic prospects (in the form of reduced supplies of more expensive food and agricultural raw materials) – an intertemporal externality – and whether this problem stems from a market failure that warrants corrective action.

A common goal of soil conservation policy is to manage soils so that erosion rates do not exceed the rate of soil formation, referred to as the soil tolerance or T value. T values will vary across soils depending on the type and climate. In contrast, as noted in the Section Intertemporal Allocation, economically efficient soil conservation may entail some depletion of soil resources. An economically efficient allocation will maximize the present value of the flow of economic returns from the use of soil. If soil were a nonrenewable resource depleted by agricultural production, and if there were no external costs associated with soil erosion, an economically efficient intertemporal allocation would equalize the present value of the marginal products of soil from period to period. In other words, soil erosion would occur at a rate that causes the value of the marginal product to grow at the social rate of discount. A natural resource that 'grows,' as soil does, can accommodate a greater rate of depletion because some of it is offset by replacement. A resource that can be fully replaced by other inputs may be depleted more quickly because increases in its marginal value ultimately will induce full replacement by those substitutes.

In an economy where social and private incentives are fully aligned, ownership is secure and markets both temporal and intertemporal function smoothly, farmers would maximize the value of their operations by degrading soil at the socially optimal rate. However, real economic settings fall short of the ideal. Individuals face greater personal risk than society in general, which may lead to higher rates of personal discounting. Market values do not always accurately capture social values. Future prices and technologies are difficult to predict. In these ways, markets may fail to induce socially optimal decisions, including decisions about the conservation of soil. It is not clear that these failings are worse for agriculture and soil than for other sectors and resources. Unlike environmental externalities, the case for intervention in private soil conservation decisions is not transparent. Countries in which governments have taken a major role in directing food production do not inspire confidence that intervention will lead to more conservative practices.

Nevertheless, the cause of soil conservation has been taken up by governments in many nations. Approaches often include efforts to educate farmers and equip them with conserving technologies, such as reduced tillage practices (Baumhardt, 2014). In some cases, governments subsidize conservation practices. Punitive approaches to soil degradation are rarely, if

ever, used. The subsidization of conservation practices is problematic in several respects. As with other subsidies, it sustains a larger agricultural industry than may actually be efficient in the long run. It also tends to be unselective – providing uniform subsidies irrespective of the variation in benefits achievable in different settings.

Historically, soil conservation policies were motivated by concern about the impact of soil erosion on farm income, rural economic well-being, and sustainability of food supplies. However, eroded soil degrades water resources, and the offsite externality cost can significantly exceed the onsite productivity cost (Ribaudo, 1986). The case for soil conservation policies based on water quality protection has supplanted the historical motivation to some degree.

Water Supply

Water is essential for agricultural production. In humid regions, water is generally amply provided by nature, though periodic droughts can cause problems. In drier regions, water must be acquired. In some regions, water may be available from groundwater sources. Groundwater stocks are renewable resources that are depleted by pumping but can be recharged by infiltration of rain and snow. Like soil, an optimal allocation over time will maximize the present value of the flow of economic returns from water use. In optimal usage, the marginal benefit of extraction less the costs of pumping at any time should equal the social opportunity cost of extraction. The social opportunity cost is the present value of the future benefits forgone at the margin due to current use. Another source of water for agriculture in arid regions is from surface water taken from streams or lakes. Lakes may be natural or created to capture and store water. The economics of surface water management may entail dynamic elements when water can be stored and used over time. A key issue in the efficiency of both surface and groundwater management is allocation among competing uses. Competing uses include agriculture, energy production, industry, and domestic use. A competing use that is being recognized in some places is instream services. These include flows for recreational uses (e.g., white water rafting) and to maintain flow-dependent aquatic ecosystems.

As with all natural resources, a key consideration in determining the efficiency of water use is the nature of property rights (Anderson *et al.*, 2013; Griffin, 2006). Property rights structures vary greatly across countries, and sometimes within countries. For example, surface water in the United States is generally owned by someone. In water-rich Eastern United States, rights have historically been governed by the Riparian Doctrine. Under this doctrine, surface water rights attach to riparian land owners. These rights are typically not fixed quantitatively but require reasonable use. The riparian approach does not serve well when water becomes scarce relative to demand and water must be allocated among competing uses. In consequence, many Eastern States have developed water management plans that set priorities for water use, and require water users to obtain permits. In contrast, surface water is private property in some western states where the prior appropriation doctrine governs rights. The principles of this system are that water rights are transferable, involve quantification, and claims over water are determined by seniority. Some western states blend the riparian and prior appropriations doctrines. A third form found in many irrigation districts and some river basins is correlative shares. In this case, private property rights exist as a share in the available resource. In addition to defining and regulating private property rights, governments designate some water resources as state property and the federal government is held to have certain reserved rights to water. The FBR developed reservoirs in western states beginning in the early 1900s through midcentury, and conveyances to supply water to various users including irrigators. FBR reservoirs are managed for multiple uses (irrigation, flood control, power generation, public water supply, and environmental flows) with evolving priorities. Variants of surface water law are found in groundwater law.

A major concern in water use is generally inefficient allocation among competing uses, and in the case of groundwater stocks, over time. In some cases, this concern emerges because of open access to water. In many agricultural regions groundwater resources are open access resources. Economic theory predicts that individual users of open access resources do not have adequate incentives to conserve. The result is excessive depletion. Empirical tests sometimes find this result, but some also find that the economic cost of open access use is small. This result is known as the Gisser-Sanchez (1980) effect after a research publication that first found this relationship. The economics profession is generally favorable toward the use of markets for water allocation compared with administrative mechanisms, but variability in water supplies and externalities that result from water allocation across space (e.g., instream flows) and time (e.g., effects of groundwater depletion on salt water intrusion in coastal aquifers) can pose challenges to the design of efficient property rights and water institutions (Griffin, 2006).

Summary and Conclusion

As the leading use of land and water, agriculture has very significant impacts on the environment and natural resources. It is a leading source of pollution discharges to water, a profound disruptor of wildlife habitats, and is increasingly recognized as a contributor to GHG emissions. In contrast, agriculture can also contribute to landscapes, amenities, wildlife that depends on agroecosystems, and carbon sequestration. Many agriculturalimpacts on the environment are difficult to measure, monitor, and attribute to specific sources, and this creates fundamental difficulties for the application of policies to discourage or restrict practices that cause environmental problems.

In general, there has been a marked reluctance to address the negative effects of agricultural activity through taxes or regulation. Instead, policymakers have tended to rely on incentive payments and voluntary participation in schemes that attempt to improve environmental performance. Nevertheless, the design of policies to address the distinctive environmental challenges of agriculture is a field of active development and experimentation. Economic concepts and methods have considerable value in this process of innovation.

Glossary

Alluvium A loose sediment deposited by moving water, such as during a flood event.
Available water capacity (AWC) The amount of water that is held in the root zone that can be extracted by plants.
Cation exchange capacity (CEC) The capacity of soil to hold nutrients, which is measured in terms of total amount of cations (positively charged ions) that a soil can retain exchangeably.
Colluvium A loose sediment transported under the influence of gravity, such as material washed down a hillslope.
Dispersion The complete disintegration of soil aggregates resulting in discrete soil particles.
Drainage The amount of water that is lost below the root zone.
Edaphic Of or relating to the soil, especially as it affects biota.
Evapotranspiration The sum of the direct evaporation from the soil surface and the water vapor transpired through plant leaves.
Exchangeable cations The cations that can be easily replaced or exchanged by other cations in soil, such as exchangeable Ca and Mg.
Field capacity (FC) The amount of water after excess water has drained away, in the laboratory commonly measured between −10 to −33 kPa.
Horizon A layer of soil, usually parallel to the ground surface, which has a unique set of morphological features making it distinguishable from other soil layers above it or below it.
Hydraulic conductivity The rate of water flow per unit gradient of hydraulic potential.
Permanent wilting point (PWP) A point where plants cannot exert the energy to remove water from the soil, in the laboratory measured at −1500 kPa.
pH A measure of acidity or alkalinity in soil, soils with pH < 7.0 are acidic and > 7.0 are alkaline.
Saturated hydraulic conductivity The saturated rate of flow of water per unit gradient of hydraulic potential.
Slaking Collapse of soil aggregates in water to form microaggregates.
Soil solution A liquid phase of the soil, mostly water with small amounts of dissolved ions.
Weathering The alteration of rocks and minerals through a variety of physical and chemical processes, resulting in the formation of soil minerals and horizons.

Introduction

The loose, mineral-rich skin of the Earth, soil, is the key component of the terrestrial ecosystem and serves numerous functions at the interface between the biosphere, hydrosphere, lithosphere, and atmosphere. Because of the multifunctionality of soils, there is not a unique definition for soil. For example, farmers use soil as a medium for growing plants for food and fiber; engineers use soils for the physical support of buildings, roads, and bridges; and soil is used as a filter for removing organic and inorganic contaminants from water or other media by various industries. From the agricultural production perspective, soil can be defined as 'the unconsolidated mineral or organic material on the immediate surface of the Earth that serves as a natural medium for the growth of land plants' (SSSA, 2013). In this context, soil serves many functions, including supplying water, nutrients, and oxygen to plants. The ability of a soil to supply essential plant nutrients, also referred to as 'soil fertility,' is dependent on the mineralogical and chemical properties of the soil, and nutrient cycling in the soil. In addition to soil fertility, soil physical properties and the interaction between soil and water are important for supplying water and air, and for providing physical support to plants.

This article will discuss the chemical and physical soil properties that are important for plant growth and yield in agriculture. However, before proceeding to such a discussion, a more inclusive definition of soil can be previewed as "the unconsolidated mineral or organic matter on the surface of the Earth that has been subjected to and shows effects of genetic and environmental factors of: climate (including water and temperature effects), and macro- and microorganisms, conditioned by relief, acting on parent material over a period of time. A product-soil differs from the material from which it is derived in many physical, chemical, biological, and morphological properties and characteristics (SSSA, 2013)." This definition highlights the importance of the factors and processes in soil formation, and recognizes their relevance in the observed properties of soil. From this definition, one can appreciate the likely influence of the soil-forming factors and processes on relevant soil properties for plant production. Throughout this article, reference will be made to four case study soil profiles from Australia, namely, (1) Pilliga, a reddish-yellow-colored sandy soil (Lixisol, IUSS Working Group WRB, 2007; Haplustalf, Soil Survey Staff, 2010); (2) Nowley, a bright red-colored soil with contrasting attributes in the upper and lower parts (Calcisol, IUSS Working Group WRB, 2007; Rhodudalf, Soil Survey Staff, 2010); (3) Toowoomba, a dark red-colored clayey soil (Nitisol, IUSS Working Group WRB, 2007; Rhodudalf, Soil Survey Staff, 2010); and (4) Callandoon, a gray-colored clayey soil (Vertisol, IUSS Working Group WRB, 2007; Haplustert, Soil Survey Staff, 2010; **Figure 1**).

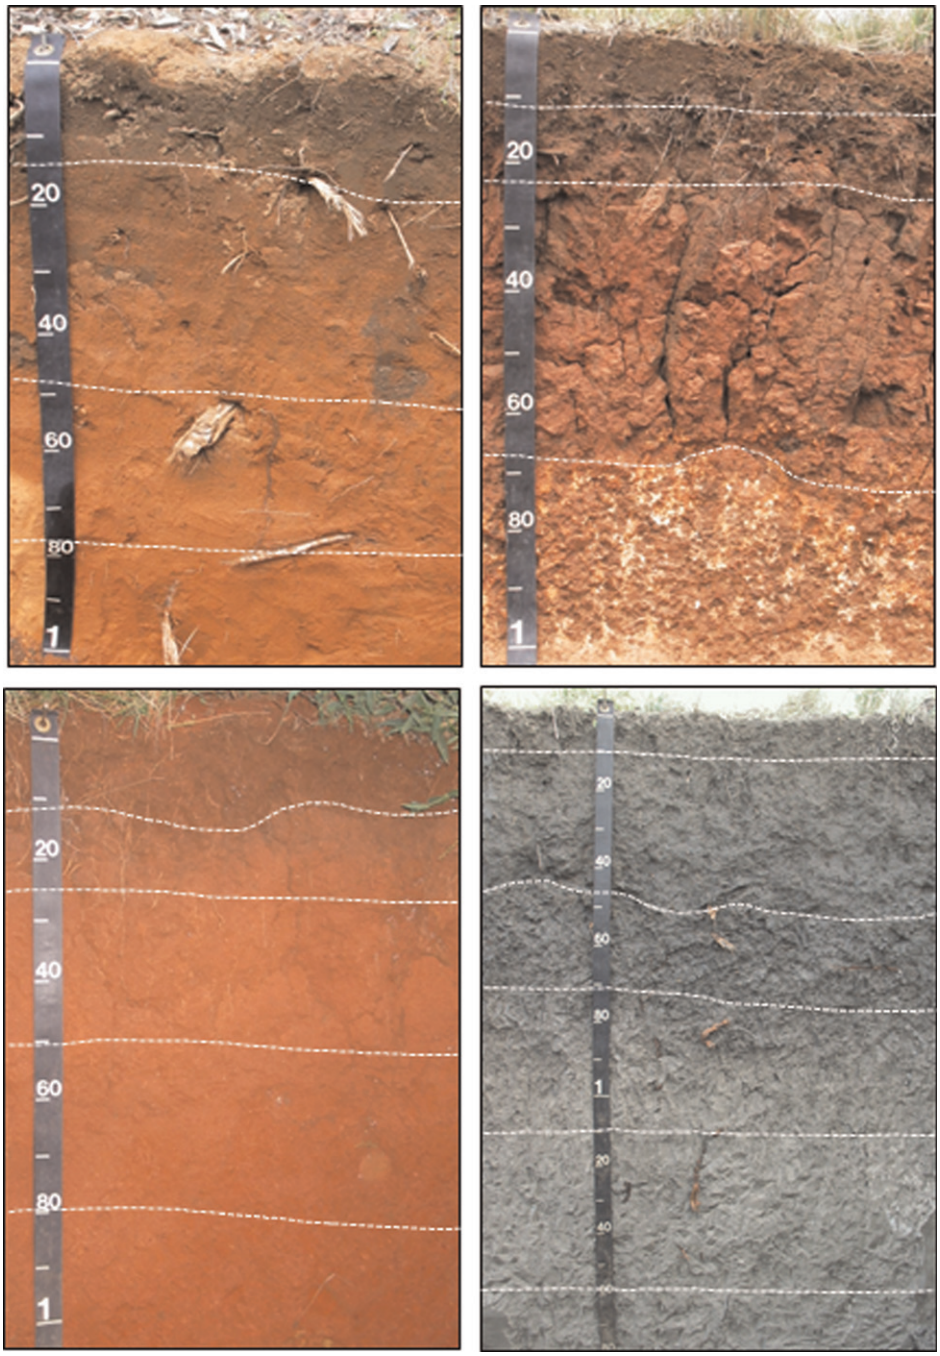

Figure 1 The four case study profiles, clockwise from top left; Pilliga, Nowley, Callandoon, and Toowoomba. The dashed lines indicate the horizon boundaries in the profiles.

Soil can be regarded as a three-phase system consisting of solid, liquid, and gas phases. To understand the chemical and physical properties and behavior of soil, it is necessary to know the proportions and types of solids present. The solid phase consists predominantly of inorganic materials with relatively smaller amounts of organic matter. The inorganic materials can be further subdivided into two parts – particles possessing a definite crystal structure (minerals) and inorganic materials that do not have any definite structure (amorphous or non-crystalline material). The amorphous fraction of soils, which may be significant in certain soils (e.g., soils derived from relatively fresh tephra deposits), is mainly composed of a mixture of variously hydrated oxides of aluminum, silicon, iron, and manganese. The crystalline fraction consists of a mixture of minerals inherited from the soil parent material and secondary minerals formed by the weathering processes within the soil.

The large variety in size and shape of solid particles and the manner in which they are arranged together produce a labyrinth of pores and channels in soils that is called pore space.

The pore space in soil is filled with either soil solution or air. The proportion of air and soil solution at any given time and place is highly variable, the quantity of one varying oppositely to that of the other. The soil solution is essentially water that contains dissolved gases and solutes of both inorganic and organic nature. In well-aerated soils the composition of soil air is quite similar to the atmosphere, except that microbial metabolism leads to higher carbon dioxide content (0.15–0.65%) in soil air compared to atmosphere (0.03%). The relative humidity of soil air is generally high.

Soil Variation in Space and Time

The exact composition and behavior of soil is highly variable due to the myriad of soil-forming processes that may operate at a given location and time. This variation manifests itself in profile thickness, the number of layers or horizons of soil in a profile, morphological attributes of the horizons (e.g., color), physical attributes of the horizons (e.g., size and arrangement of particles), chemical attributes of the horizons (e.g., pH and elemental concentrations), and the biotic fraction of the soil.

It is commonly held that the five most important soil-forming factors governing soil type and attributes are: the parent material of the soil, the climatic regime at the soil's location, the topographic position of the soil in the landscape, the influence of organisms, and the time over which the soil has been forming. The relative importance of these five soil-forming factors will vary from place to place, but there is almost always some effect of each factor on the soil's properties.

Parent Material

In many cases, the dominant soil-forming factor is the parent material of the soil. As the name suggests, soil parent materials are the hard or loose mineral materials from which soil horizons and profiles are derived. The common soil parent materials are rocks, river-borne sediment (alluvium), wind-borne sediment (eolian), hillslope sediment (colluvium), lakebed sediment (lacustrine), materials moved by glacial advance and retreat (glacial till), and volcanic ash. Obviously, for some of these parent materials to be present there must be certain topographic or climatic conditions met. But the nature of the parent material is very important to the properties and attributes of soil profiles, in particular to the suite of minerals present and the size of the soil particles. The top 20–25 km of the Earth's crust consists of approximately 95% igneous rocks or their metamorphic equivalents, 4% shale, 0.75% sandstone, and 0.25% limestone. The average chemical composition of common rocks is given in Table 1. It is evident that SiO_2 and Al_2O_3 account for >70% weight fraction of the lithosphere.

Igneous rocks are exposed mainly in mountainous areas or in lava flows and provide the bulk of the mineral substrate that is spread over the land surface by alluvial, eolian, colluvial, lacustrine, and glacial processes. Consequently, sedimentary rocks form a veneer over much of the crust covering approximately 80% of the land surface. In the case of crustal igneous rocks, silicon-based minerals, more commonly referred to as 'primary silicate minerals,' make up well over 95% of all minerals present. The average mineralogical composition of igneous rocks is 60% feldspars, 17% amphiboles and pyroxenes, 12% quartz, 4% micas, and 8% other minerals.

Table 1 Average chemical composition of major rocks of the Earth's crust

Analysis (%)	*Granite*	*Basalt*	*Sandstone*	*Shale*	*Limestone*
SiO_2	72.08	48.36	78.33	58.10	5.19
Al_2O_3	13.86	16.84	4.77	15.40	0.81
Fe_2O_3	0.86	2.55	1.07	4.02	0.54
FeO	1.67	7.92	0.30	2.45	–
MgO	0.52	8.06	1.16	2.44	7.89
CaO	1.33	11.07	5.50	3.11	42.57
Na_2O	3.08	2.26	0.45	1.30	0.05
K_2O	5.46	0.56	1.31	3.24	0.33
TiO_2	0.37	1.32	0.25	0.65	0.06
H_2O	0.53	0.64	1.63	5.00	0.77
P_2O_5	0.18	0.24	0.08	0.17	0.04
CO_2	–	–	5.03	2.63	41.54
SO_3	–	–	0.07	0.64	0.05

Note: Elemental concentrations are traditionally expressed as oxides because the analyses were done using XRF and elements were assumed in their oxide forms.
Source: Reproduced from Nockolds, S.R., 1954. Average chemical compoisition of some igneous rocks. Geological Society of America Bulletin 65, 1007–1032; Clarke, F.E., 1924. The data of geochemistry. U.S. Geological Survey Bulletin 770, fifth ed. Washington: U. S. Government Printing Office; and Klein, C., Hurlbut, C.S., 1999. Manual of Mineralogy, twenty-first ed. New York: John Wiley.

Primary minerals: Minerals formed at very high temperatures and inherited (unaltered) from igneous rocks and metamorphic rocks. These minerals usually occur in the sand (0.02 or 0.05–2.0 mm) and silt (0.002–0.02 or 0.05 mm) size fractions of the soil.

Common primary minerals in soils are as follows:

1. Feldspars – microcline, $KAlSi_3O_8$; orthoclase, $KAlSi_3O_8$; albite, $NaAlSi_3O_8$; and anorthite, $CaAl_2Si_2O_8$.
2. Quartz (SiO_2).
3. Micas – muscovite, $K(Al)_2[Si_3Al]\ O_{10}(OH)_2$, biotite, $K(Mg, Fe^{2+})_3[Si_3Al]\ O_{10}(OH)_2$).
4. Amphiboles – hornblende, $(Ca,Na,K)_{2,3}(Mg,Fe,Al)_5(OH)_2(Si, Al)_8O_{22}$).
5. Pyroxenes – augite, $(Ca,Na)(Mg,Fe,Al)(Si,Al)_2O_6$).
6. Olivines – forsterite, Mg_2SiO_4).
7. Rutile (TiO_2).
8. Zircon ($ZrSiO_4$).
9. Magnetite (Fe_3O_4).
10. Epidote $(Ca_2(Al,Fe)_3(OH)Si_3O_{12})$.
11. Tourmaline $(Na,Ca)(Li,Mg,Al)(Al,Fe,Mn)_6(BO_3)_3\ (Si_6O_{18})(OH)_4$.

The mineral composition of soils is highly variable depending on the parent material, extent, and duration of weathering, and pedoenvironmental conditions. Weathering is a complex process that occurs through physical, chemical, and biological processes. These weathering processes not only result in the transformation of primary minerals into secondary minerals, but also in the release of many essential plant nutrients, and the modification of edaphic soil properties. Goldich (1938) proposed a mineral stability series for sand

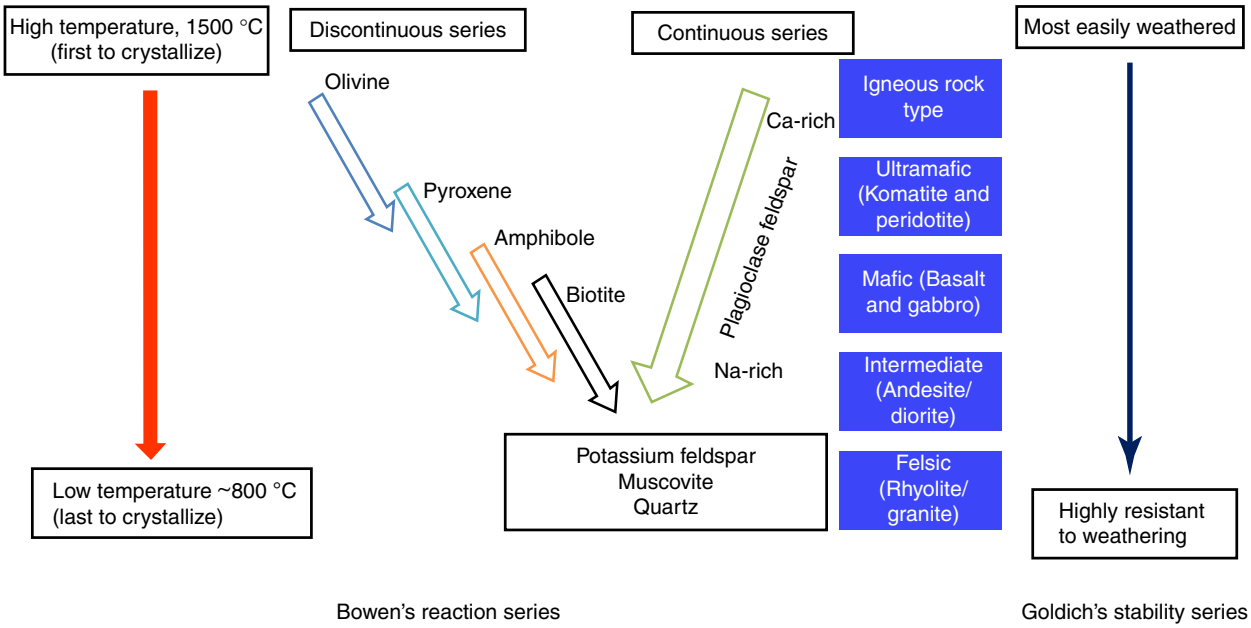

Figure 2 The stability order of primary soil minerals based on Bowen's Reaction Series and Goldich's Stability Series.

and silt particle size fractions, which is useful in predicting the stability of common primary minerals in soils. The Goldich Series is identical to the Bowen's Reaction Series that was formulated to explain the order of crystallization of the common silicate minerals from a magma. The minerals that are formed at higher temperatures (such as olivine, pyroxene, etc.) and then exposed to low temperature terrestrial conditions, will be farthest from their crystallization temperature (comfort zone), and will therefore chemically weather first. Quartz, at the other end of series, is closer to its preferred temperature and, therefore, is much more stable to weathering (Figure 2).

Parent rock in relation to soil fertility and other soil properties

In less weathered or relatively younger soils, a significant reserve of nutrient elements exist within the primary minerals. When present in the mineral structure, the nutrients are not available to plants; however, weathering processes release these nutrients very slowly to the soil solution. The mineralogical and elemental composition of igneous rocks is determined by the chemical composition of the magma from which it solidifies. Among the igneous rocks, granite and rhyolite contain relatively low concentrations of essential plant nutrients, with the exception of potassium (Table 1). In contrast, basalt and gabbro contain much higher concentrations of iron, magnesium, calcium, and many other trace elements. Thus, soils formed on basalt (or gabbro) are inherently more fertile than a soil formed on granite (or rhyolite), with the exception of K fertility.

The chemical and mineralogical composition of sedimentary and metamorphic rock is determined by the composition of the sediments and rocks from which they have originated. Sandstones and shales are generally composed of preweathered materials consisting of stable primary and secondary minerals; due to the lack of weatherable primary minerals these rocks have limited capacity to supply appreciable quantities of nutrient elements. Limestone is a rich source of Ca and Mg, and low levels of other essential plant nutrients. Ultrabasic rocks, such as peridote, olivinites, dunite, and serpentine, contain low concentration of Ca and very high concentrations of Mg, Cr, Ni, and Mn, which have a particularly strong influence on plant nutrition. Unique plant species survive on the soils formed on ultrabasic rocks and many of the plants growing on these soils have the capacity to hyperaccumulate trace metals such as Ni.

Secondary minerals: Secondary minerals in soils are formed from the weathering of primary minerals either through crystallization from soil solution or via alteration of primary minerals. These minerals often dominate in the clay fraction (<0.002 mm or 2 μm) of the soil and are often referred to as clay minerals.

Some common secondary minerals in soils are as follows:

1. Kaolinite – $Al_2Si_2O_5(OH)_4$.
2. Smectite – variable (layer charge between 0.2 and 0.6 per $O_{10}(OH)_2$, an ideal montmorillonite- $Na_{0.4}(Al_{1.6}Mg_{0.4})(Si_4)O_{10}(OH)_2$
3. Vermiculite – variable (layer charge between 0.6 and 0.9 per $O_{10}(OH)_2$, an ideal dioctahedral vermiculite – $Na_{0.7}(Al_2)(Si_{3.3}Al_{0.7})O_{10}(OH)_2$.
4. Goethite – α-FeOOH, the substitution of Al is very common in highly weathered soils and common composition is close to -α-$(Fe_{0.75}Al_{0.25})OOH$.
5. Hematite – α-Fe_2O_3, the substitution of Al is very common in highly weathered soils and common composition is close to -α-$(Fe_{1.9}Al_{0.1})_2O_3$.

Among the four profiles, only the Callandoon soil contains feldspars (microcline and albite) throughout the profile, all soils contain quartz with only trace amounts in the Toowoomba soil, and calcite is present at depth in the Nowley soil.

The four case study soils also provide good examples of the effects of different parent materials on soil attributes such as particle size distribution. The coarse-grained Pilliga profile is derived from the weathering of coarse-grained sandstone rock, whereas the texture-contrast Nowley profile is derived from a mixture of sandstone and basaltic colluvium. The fine-grained Toowoomba profile is derived from the weathering of fine-grained basalt rock, and the very fine-grained Narrabri profile is derived from basaltic alluvium.

Climate

Climate can have a substantial effect on soil profile development through the transformation, alteration, and movement of mineral solids and solutes inherited from the soil's parent material. From a soil formation standpoint, the two most important climatic factors are rainfall and temperature. As the amount of annual rainfall increases, so does the opportunity for topsoil organic carbon content to increase, for the washing of very small particles into the subsoil to occur, for the leaching of solutes to occur, and for the development of morphological features (e.g., color mottles or patches, nodules of Fe and Mn oxides) to occur due to fluctuating redox conditions in the soil. Such processes are very important for the development of multiple horizons in one soil profile. The effect of increasing temperature on the rate of chemical reactions in the soil shows that soil is important for soil development. In locations with higher air and soil temperatures, both the rate of organic matter decomposition and the rate of mineral transformation are faster. Soils of the equatorial tropics are commonly strongly weathered due to the high rainfall, high temperature climatic regime, with a preponderance of low charge clay minerals and iron oxides, both products of primary mineral breakdown. Under rainforest vegetation, such soils contain moderate organic matter contents at the soil surface. But with clearing and cultivation the supply of organic matter from the vegetation canopy to the topsoil decreases sharply, followed by a rapid decrease in soil organic matter (SOM). It follows, then, that soils with the greatest accumulation of organic matter in the topsoil are located in wet, cold locations. The high latitude, boreal regions of North America, Europe, and Asia, which are characterized by long cold winters and short cool summers, are home to extensive areas of organically dominated peat soils (Driessen and Dudal, 1991). In contrast, soils of dry, hot climatic regimes, such as those experienced in the deserts of northern Africa, the Middle East, and Asia are characterized by low organic matter contents and the accumulation of readily and sparingly soluble salts, including gypsum and lime (Driessen and Dudal, 1991).

Topography

The role of topography in soil formation is to mediate the development of horizons through effects on water and solute flow, and particle movement. In sloping landscapes with moderate to high rainfall, leaching of solutes and the washing of solids down the profile and across the soil surface leads to greater differentiation of topsoil and subsoil horizons in both chemical and physical attributes. Soluble salts and fine-grained particles tend to be transported to lower horizons and lower points in such landscapes, whereas insoluble materials and large-grained solids (including gravel) tend to be retained in upper horizons and landscape positions. In flat landscapes, deposition and organization of sediment is favored. Depending on the sediment grain size, imperfect drainage of water in flat areas can lead to the development of particular mineral suites. The Callandoon profile is a good example of this, with the fine-grained alluvial parent material favoring the formation and longevity of the shrink-swell mineral smectite.

Organisms

The soil formation factor of organisms is a requirement in all soils, as soil is differentiated from other loose regolith materials (e.g., fresh sediment) by the presence of vertical differentiation due to biotic activity. Although soil formation is rarely dominated by this factor, there are nevertheless many ways in which organisms may affect soil development. Plants, microorganisms (e.g., fungi and bacteria), mesofauna (e.g., earthworms and ants), macrofauna (e.g., burrowing animals and hoofed livestock), and humans are all responsible for altering physical and chemical properties of soil horizons under certain circumstances. In many agricultural landscapes, it is likely that of all the groups of biota humans have had the greatest impact: land clearing and cultivation leads to the mixing of soil horizons, changes to the hydrologic cycle, changes to the physical condition of the topsoil, and changes to nutrient cycling; the use of fertilizers alters the chemical status of the topsoil horizons; and irrigation alters the redox potential of the soil and nutrient cycling within the profile. Nevertheless, the other groups of biota also contribute to important effects in some situations. Plants improve the physical condition of topsoil through the binding effect of growing roots and the addition of organic matter through leaf litter. Microorganisms are responsible for organic matter breakdown and catalyze various chemical reactions in the soil. Mesofauna create continuous passages in soil, redistribute plant nutrients around the profile, and turns over topsoil. Macrofauna can exacerbate soil erosion by pulverizing the surface soil or burrowing into unstable subsoils (Hole, 1981).

Time

The final soil formation factor, time, is perhaps the most difficult to interpret without highly specific soil dating data. However, in concert with the other soil-forming factors, elapsed time is a crucial determinant of soil profile differentiation; the longer the soil parent materials have existed at a location, undergoing a range of soil-forming processes, the greater the likelihood that the soil will be well differentiated, with greater horizonation and usually more contrasting topsoil and subsoil horizons. Older soil profiles also tend to contain a greater proportion of resilient minerals, and secondary minerals that are breakdown products of less resilient minerals. Again, soils of stable landscapes in the tropics commonly express these attributes, with deep, brightly colored profiles containing much kaolinitic clay, and iron and aluminum oxides and hydroxides, all of which are resilient

secondary minerals (Driessen and Dudal, 1991). The bright red colors apparent in the Nowley and Toowoomba profiles are also a consequence of the formation of iron oxides through weathering of less resilient minerals over long periods of time.

Key Edaphic Soil Properties

One of the unique features of soil as a natural body is that profiles are assemblages of horizons (Churchman, 2010). The number of horizons in a soil profile can vary widely, but it is common for a profile to have four to six horizons in the top 1.5 m. Horizons are normally distinguished based on easy-to-assess morphological properties such as color, texture, and structure. In some soil types the horizons are largely unchanging with depth (e.g., Toowoomba and Callandoon profiles), whereas in others horizon attributes change markedly from the topsoil to the subsoil (e.g., Nowley profile in Figure 1). Although there are many different soil classification schemes used around the world, in virtually all of them an 'ABC' nomenclature is used, where the A horizons are surface or near-surface horizons showing evidence of organic matter enrichment, the B horizons are subsoil horizons showing greater color saturation or an accumulation of clay or better developed structure, and C horizons are largely unaltered parent material. In full soil profile descriptions, subdivisions of the A and B horizons are normally made based on changes in various morphological and chemical features, and in many soil classification schemes it is the presence of certain horizon types that dictates the allocation of a soil profile to a class. Two of the soil classification schemes most widely used around the world are the World Reference Base for Soil Resources (WRB) (IUSS Working Group WRB, 2007) and Keys to Soil Taxonomy (Soil Survey Staff, 2010), and both use topsoil and subsoil horizon types as the basis of soil-type allocation. Many of the most important edaphic soil properties are also used to describe certain horizon types. These key edaphic soil features are now discussed and how they are described in soil horizons and profiles is shown.

Texture

In soil science terms, texture is a particular combination of clay-, silt-, and sand-sized particles in a horizon. In common parlance it can be thought of as the feel of the soil, and it is a property usually assessed in the field. In most soil description systems there are between 10 and 20 different texture grades used. Using the Nowley soil profile as an example, the texture grade for the top horizon is clay loam and for the other three horizons it is clay. Although there are some slight differences in how silt- and sand-sized are defined around the world, a sand-sized particle is commonly defined as having a diameter between 2000 and 50 μm, a silt-sized particle has a diameter between 50 and 2 μm, and a clay-sized particle has a diameter less than 2 μm (Figure 3). Strictly speaking, the words 'clay', 'silt,' and 'sand' only refer to particle size, but it is common for soil scientists to associate various minerals with these different size fractions. For example, the difficult-to-weather mineral quartz is a very common component of the sand fraction in soils, whereas sheet silicate minerals such as kaolinite and smectite, which form in soil, usually exist in the clay fraction. The clay content is one of the most important attributes used to differentiate different horizons and subhorizons, and therefore to differentiate between different soil classes, or types. The Callandoon soil profile contains more than 40% clay in all horizons, leading to its classification as a Vertisol.

As an edaphic property, texture is critically important for a variety of reasons. From a physical standpoint, the texture profoundly influences water infiltration rate and conductivity, water storage, soil density, and soil strength. From a chemical standpoint, texture is very strongly linked to the availability of various plant nutrients. Generally speaking, the more clayey a horizon, the more likely it is to retain or hold both water and plant nutrients. These edaphic linkages will be explored in more detail in the following sections.

Structure

Texture refers to the size of soil particles, whereas structure refers to the spatial arrangement of those particles and the voids (pores and cracks) between them. Another unique feature of soil as a natural material is that individual particles aggregate together through a range of processes at various scales to yield 'peds' (Churchman, 2010) or 'aggregates.' The degree of pedality (strong, medium, weak, and apedal) is often assessed visually in the field, as is the dominant ped shape and size in each horizon. In most soil description systems, there are approximately 10 different ped shapes used. Clear examples of angular blocky peds (cube-like shape) can be seen in the red-colored third horizon of the Nowley profile, whereas the Pilliga profile lacks any discernible peds and is described as apedal. Together with an estimation of the pore volume and size of individual pores, these ped attributes give a qualitative account of the 'structural form' of a soil horizon. Like texture, structure is an important diagnostic property for the identification of certain horizon and profile types.

The stability of peds (aggregates) in a soil horizon depends on the way the sand-, silt-, and clay-sized particles are organized and the binding agents between these. It is commonly accepted that microaggregates (2–250 μm) are comprised of clay minerals that are bound together by either the presence of exchangeable cations on the clay surfaces or organic polymers bridged by polyvalent cations (e.g., Ca^{2+} and Al^{3+}) interacting with the clays (Figure 4). The presence of calcium carbonate ($CaCO_3$) and sesquioxides (Fe and Al oxides) also provide cohesion of microaggregates. Macroaggregates (250–2000 μm) are comprised of cohesive microaggregates and are primarily stabilized through enmeshment by plant roots and fungal hyphae. For soils with a pH range of 5.5–7, soil management that promotes a high level of biological activity (e.g., root growth, fungi, and microorganisms) will benefit aggregate stabilization and, in particular, macroaggregates. Also, avoiding management practices that result in the dominance of monovalent cations (e.g., Na^{+}) on the clays and the loss of soil carbon will promote cohesive microaggregates. At higher pH, $CaCO_3$ plays a crucial role and at lower pH, Fe and Al oxides will contribute to aggregation.

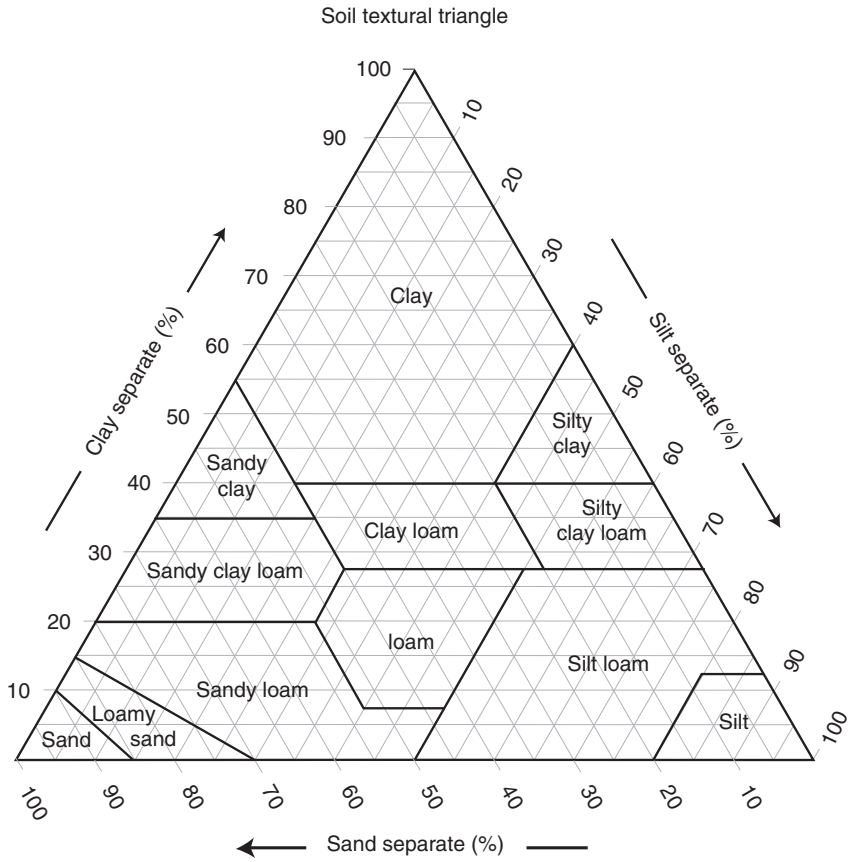

Figure 3 The soil textural triangle based on the USDA system, where sand comprises the 2.0–0.05 mm (50–2000 μm) fraction, silt 0.05–0.002 mm (2–50 μm) fraction, and clay the fraction which has a diameter less than 0.002 mm (<2 μm) (http://www.nrcs.usda.gov/wps/portal/nrcs/detail/soils/edu/kthru6/?cid=nrcs142p2_054311).

When aggregates are exposed to water, the stresses imposed may result in structural instability, leading to slaking or dispersion. Slaking is a physical phenomenon where aggregates essentially fall apart to form smaller macro- or micro-aggregates. In some situations slaking can be a desirable structural regeneration process, but if there is excessive slaking resulting in fragments <100 μm diameter, there is the potential for the soil to form surface seals, which will reduce water infiltration. Dispersion is a physicochemical process where individual particles within peds completely dissociate from each other on wetting, due to low electrolyte concentrations in the soil water and a surplus of exchangeable Na^+ on the surfaces of clay minerals. In these situations, the soil is said to have a high exchangeable sodium percentage (ESP), meaning that Na^+ comprises a larger proportion of the cation exchange capacity (CEC) than is normal (for sodic soils ESP > 15%). When such soil is wetted, the Na^+ present causes repulsive forces to overcome the strength of aggregation, leading to dispersion. Two other forms of structural instability are differential swelling and mechanical fragmentation. In the case of differential swelling, also referred to as mellowing, it is usually regarded as a desirable process as it increases the friability of the soil (Figure 4). The process of differential swelling depends on the rate of wetting and the presence of binding agents that hold the aggregates together. The main driving force is the presence of clay minerals that have a large swelling potential and this enables the aggregates to not be disrupted by the entrapped air within them (Figure 4). Finally, the exposure of wetted aggregates to the kinetic energy of raindrop impact will often result in their disruption and this is identified as mechanical fragmentation (Figure 4).

The structural form and stability of a soil are the key determinants of the soil's ability to support plant life. As is the case with texture, soil structure has a profound influence on water and gas movement in and through the soil, water storage, soil density, and soil strength. In turn, these properties dictate the ease with which seedlings germinate, the rooting patterns of growing vegetation, the ease with which plant roots extract available water, and the propensity of soil horizons to become waterlogged and anoxic.

Pore Space Relations

Together, the texture and structure of soil horizons govern the particular arrangement of the three phases of the soil, namely, the soil solids, soil solution, and soil air (Figure 5).

The arrangement of the soil particles provides the framework for the other phases and the assessment of this arrangement should provide useful information about the other phases. As can be seen in Figure 5 the total mass is comprised of the mass of the solid phase (M_s) and mass of any water

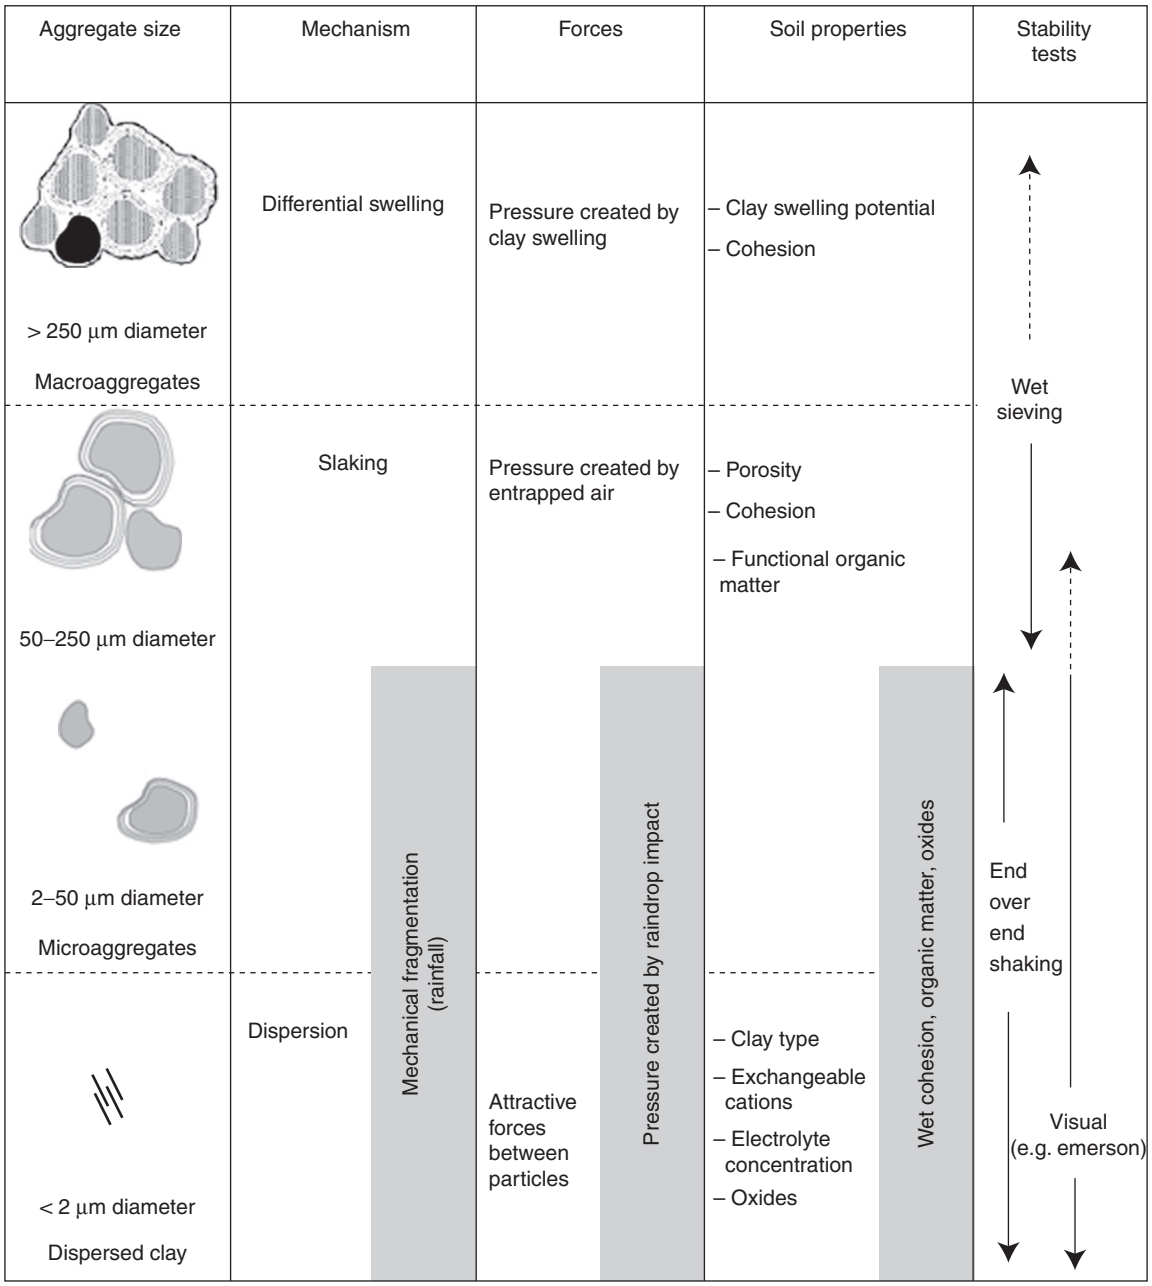

Figure 4 A summary of the major forces responsible for aggregate breakdown and dispersion, and the stability tests that may be employed to assess this. Reproduced from Field, D.J., 1999. Aspects of aggregate stability: Mechanisms, associated physico chemical properties, and assessment. In: Cattle, S.R., George, B.H. (Eds.), Describing, Analyzing and Managing Our Soil. Sydney, NSW: University of Sydney Publishing, pp. 135–148.

(M_w) present. The mass of air (M_a) by comparison is negligible and is not considered.

There are a range of minerals that make the soil solids and the measurement of these is known as the solid density (ρ_s), or mean particle density

$$\rho_s = \frac{\text{Mass of solid}}{\text{Volume of solid}} = \frac{M_s}{V_s} \quad [1]$$

The range of solid densities for some of the common minerals found in soil are given in Table 2, and a more comprehensive list of the solid densities of soil minerals can be found in Cresswell and Hamilton (2002). For most soils the coarse fraction is dominated by quartz and the fine fraction by the clay minerals (e.g., smectite, illite, and kaolinite) and all these minerals have similar ρ_s. The dominance of these minerals means that it is generally accepted that a ρ_s of 2.65 Mg m^{-3} is the value for density for the soil solids. In some soils the increased presence of iron oxides (e.g., hematite) will increase the ρ_s, whereas a dominance of organic matter may lower the ρ_s.

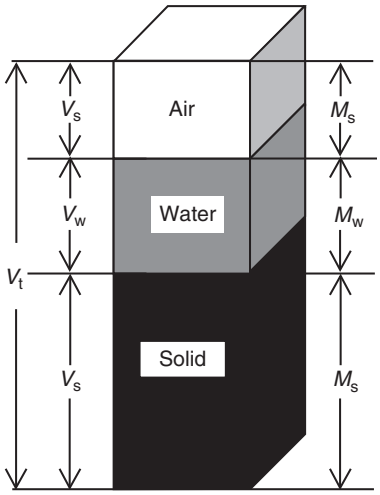

Figure 5 A schematic representation of the three phases in soil, where each phase can be measured as having a mass (M) and occupying a volume (V). Adapted from Hillel, D., 2004. Introduction to Environmental Soil Physics. Amsterdam: Elsevier Academic Press.

Table 2 Solid density for common soil minerals

Soil particle	*Solid density (Mg m^{-3})*
Quartz	2.65
Smectite	2.50
Kaolinite	2.60
Illite	2.50
Goethite	4.37
Hematite	5.26
Calcite	2.71
Gypsum	2.32
Halite	2.16

As described earlier, the soil structure is often evaluated using a description of size and shape of the soil peds, but the solid phase can also be measured in terms of its bulk density and is expressed as

$$\rho = \frac{\text{Mass of oven dry soil}}{\text{Total volume}} = \frac{M_s}{V_t}$$
$$\rho_s = \frac{\text{Mass of solid}}{\text{Volume of solid}} = \frac{M_s}{V_s} \quad [2]$$

The development of a pore phase when the soil solids are aggregated means that the bulk density (ρ) is always less than the solid density (ρ_s). The pore space can occupy from 30% to 60% of the total volume, resulting in a range of bulk densities. A broad relationship between bulk density and different texture grades has been developed and generally, an increase is the amount of silt or clay in a soil will result in a greater range of ρ and the distribution of pores that will develop when a soil is aggregated. The presence of clay that will swell and shrink in response to changes in moisture will also affect the ρ.

Soils with uniform textures throughout the profile usually show small changes in the bulk density with depth (Figure 6 (b), (c), and (d)). For uniformly clayey soils an increase in bulk density with depth may indicate the development of compaction, which can be the result of overburden pressures from the use of farm machinery in crop management (Figure 7 (c)). This problem has resulted in the adoption of controlled traffic practices, which ensure that the area of the field being affected by the excess weight of machinery is limited, avoiding increases in the ρ that will constrain root development. Profiles where there is naturally significant increase in clay content with depth may exhibit an increase in bulk density (Figure 6 (a)) and this is seen as quite normal.

The bulk density of the soil and the resulting porosity will affect how water and gas move through the soil and how easy it is for roots to penetrate the soil. The porosity of the soil is expressed using the relationship

$$\phi = \frac{\text{Volume of voids}}{\text{Total volume}} = \frac{(V_a + V_w)}{V_t} \text{or} \left(1 - \frac{\rho}{\rho_s}\right) \quad [3]$$

The pores and cracks that exist between soil aggregates are known as macropores and these are usually created by soil fauna, plant roots, or the shrinking and swelling of the soil (Table 3). The smaller pores that exist within aggregates are called micropores and these are responsible for storing the water in soil. The distinction between pores that freely drain as opposed to those that store water can be used to distinguish macropores from micropores, respectively (Table 3).

Having sufficient moisture in soil is a major limiting factor affecting plant growth in agricultural systems. It is estimated that up to 50% of the global surface is used for dryland agriculture and therefore having soil that can maximize its water storage capacity without the option of supplementary supply via irrigation is critical to most production systems.

Water in soil exists in the soil pores and the amount of water can be expressed as a mass or a volume. The mass of water in a soil is referred to as the soil's wetness (w) in g g^{-1}, whereas the volumetric water content reports water in terms of the volume (θ) it occupies in m^3 m^{-3}, both being expressed as follows

$$w = \frac{\text{Mass of water}}{\text{Mass of solids}} = \frac{M_w}{M_s} \text{ and } \theta = \frac{\text{Volume of water}}{\text{Total volume}} = \frac{V_w}{V_t} \quad [4]$$

As will be seen later, expressing water content on a mass basis will prove useful when correcting for water in the soil laboratory, but the use of volumetric water content is more useful biologically and agriculturally.

If the bulk density of the soil is indicative of the amount of pore phase, the volume of water in a soil can be calculated if we know the mass of water it contains, as follows;

$$\theta = \omega \times \rho \quad [5]$$

In addition to using eqn [3] to calculate ∅ when a soil is saturated, the amount of water is equal to the soil's porosity and this is identified for the four soil profiles in Figure 7.

The uniform texture of the Pilliga, Callandoon, and Toowoomba soil profiles has resulted in very little change in the overall porosity throughout the respective profiles (Figure 7(b), (c), and (d)). The decrease in the porosity with depth for Nowley (Figure 7(a)) is the result of the increased bulk density

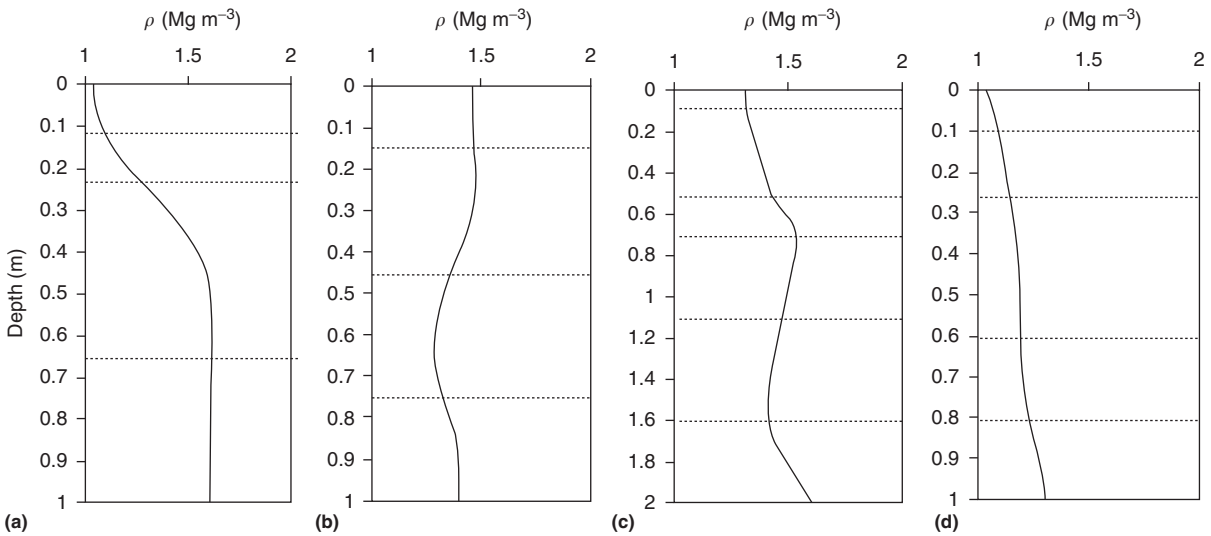

Figure 6 Change in bulk density with depth for the soil profiles. From (a) Nowley, (b) Pilliga, (c) Callandoon, and (d) Toowoomba.

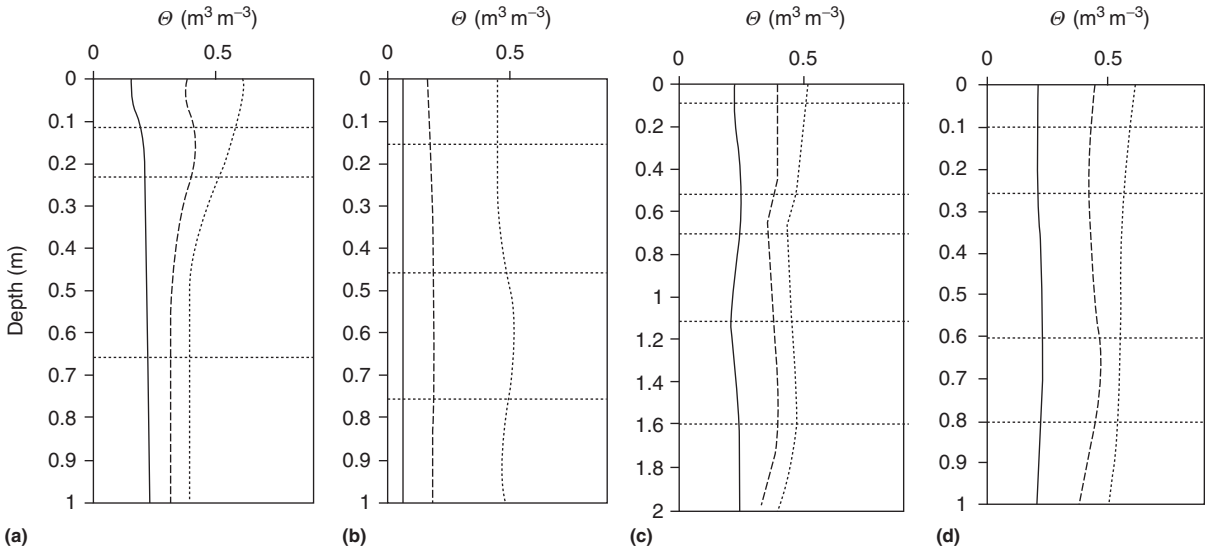

Figure 7 Change in the permanent wilting point (PWP) (solid line), field capacity (FC) (- - - -), and total porosity (————) with depth for the soil profiles. From (a) Nowley, (b) Pilliga, (c) Callandoon, and (d) Toowoomba.

Table 3 The relationship between pore size and functions in soil

Pore diameter (μm)	*Associated biotic agents functions*
5000–500	Earthworm channels and main plant roots; pores for rapid drainage and aeration
500–30	Grass roots and small mesofauna; normally draining pores
30–10	Fine lateral grass roots and fungal hyphae; very slow drainage pores
10–0.2	Root hairs, fungal hyphae, and bacteria; 'available water'
<0.2	Shrink-swell water in clays; residual water or 'nonavailable water'

Source: Reproduced from White, R.E., 2003. Soils for Fine Wines. New York, NY: Oxford University Press.

of this soil. In Figure 7, the term field capacity (FC) is used to describe the maximum amount of water the soil can store. It is clear that the difference between the amount of water at saturation (equivalent to the porosity) and the FC for the sandy Pilliga profile is very large compared to the soils with more clay. This is because packing of the sand grains results in larger pores that transmit water but are not able to store it. The pore size range of loam and clay soils is greater, resulting in more pores that can store water compared to sands. This can be seen in Figure 7 if the area between the FC and what is identified as the permanent wilting point (PWP), which is the point where plants cannot exert enough energy to remove water from soil surfaces and pores is compared. For the Pilliga profile, this area is less than that for the clayey Callandoon and Toowoomba soils, meaning that overall there is less available water in this profile

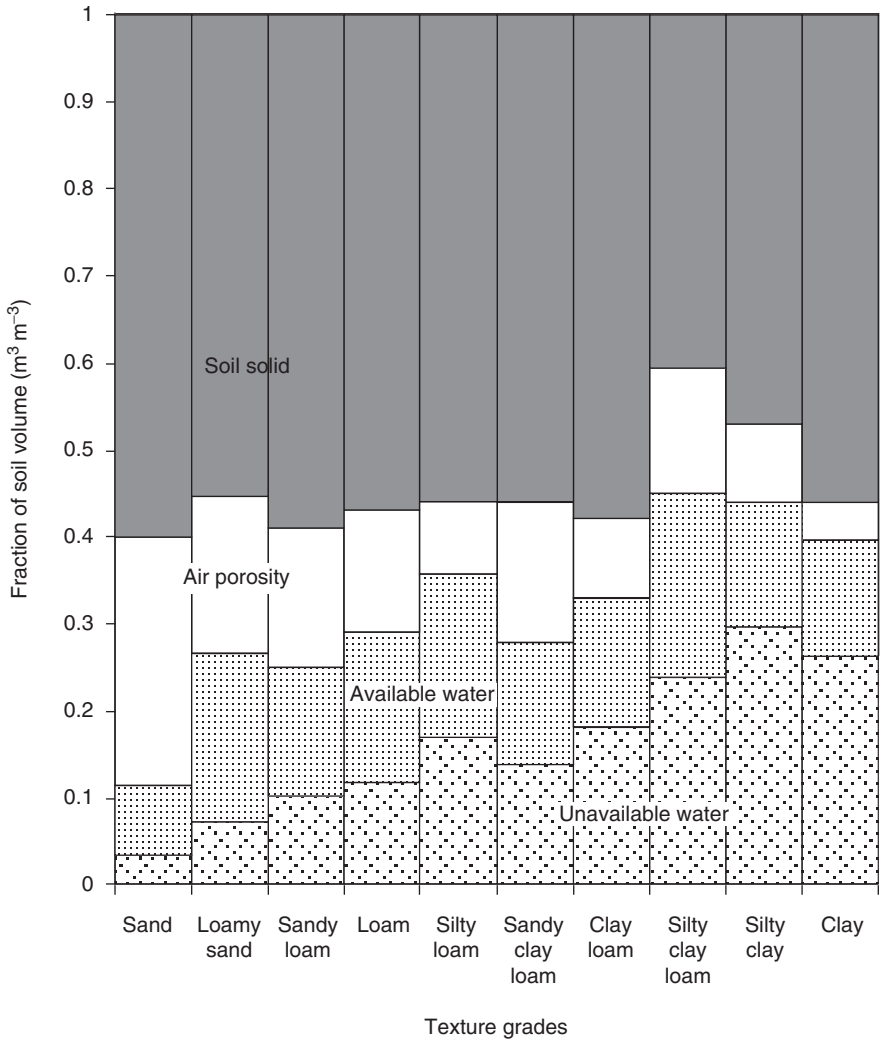

Figure 8 A representation of the volume occupied by the unavailable water, available water, air porosity, and soil solids for a range of soil textures.

(Figure 7(b), (c), (d)). To quantify this the potential volume of the soil that can hold water and what forces are acting on the soil to move water around, or the water potential are considered.

Soil Water Storage

A simplified illustration of the amount of water that can be stored in soil for a range of textures is presented in Figure 8. The difference in the amount of soil water stored (Figure 8) not only depends on the amount of pores present as discussed earlier but also the forces that are responsible for moving water into and through the soil.

Gravity is the dominant force that moves water into and through the soil when wet, exerting a force that is proportional to the height of water above the soil surface. This is known as the gravitational potential (ψ_g). Once water has entered the soil its storage is mainly affected by adsorption forces and the soil's capillarity. The adsorption of water when the soil is very dry is mainly due to the hydrogen bonding of water molecules to each other and the soil particle surfaces. This surface adsorption occurs because soil particles often carry negative charge, which attracts cations that are surrounded by a hydration shell of water molecules. Because soil particles have a specific surface area and are often charged means that plants have to exert energy to remove water from these surfaces. The larger specific surface area and potential surface charge usually present in clayey soils results in more water being unavailable compared to sandy soils, as the plants cannot overcome the adsorption energy of the soil surfaces.

The capillarity is a consequence of the particle geometry and attraction of solid surfaces for water. Pores can hold water if the air-water meniscus can hold up the column of water beneath it (Figure 9(a)). The combined effect of adsorption and capillarity on the free energy of water is described as the matric potential, ψ_m, and can be directly related to the pore radius. Usually, soil horizons with loamy texture grades have a pore size distribution that holds the most available water compared to clays and sands.

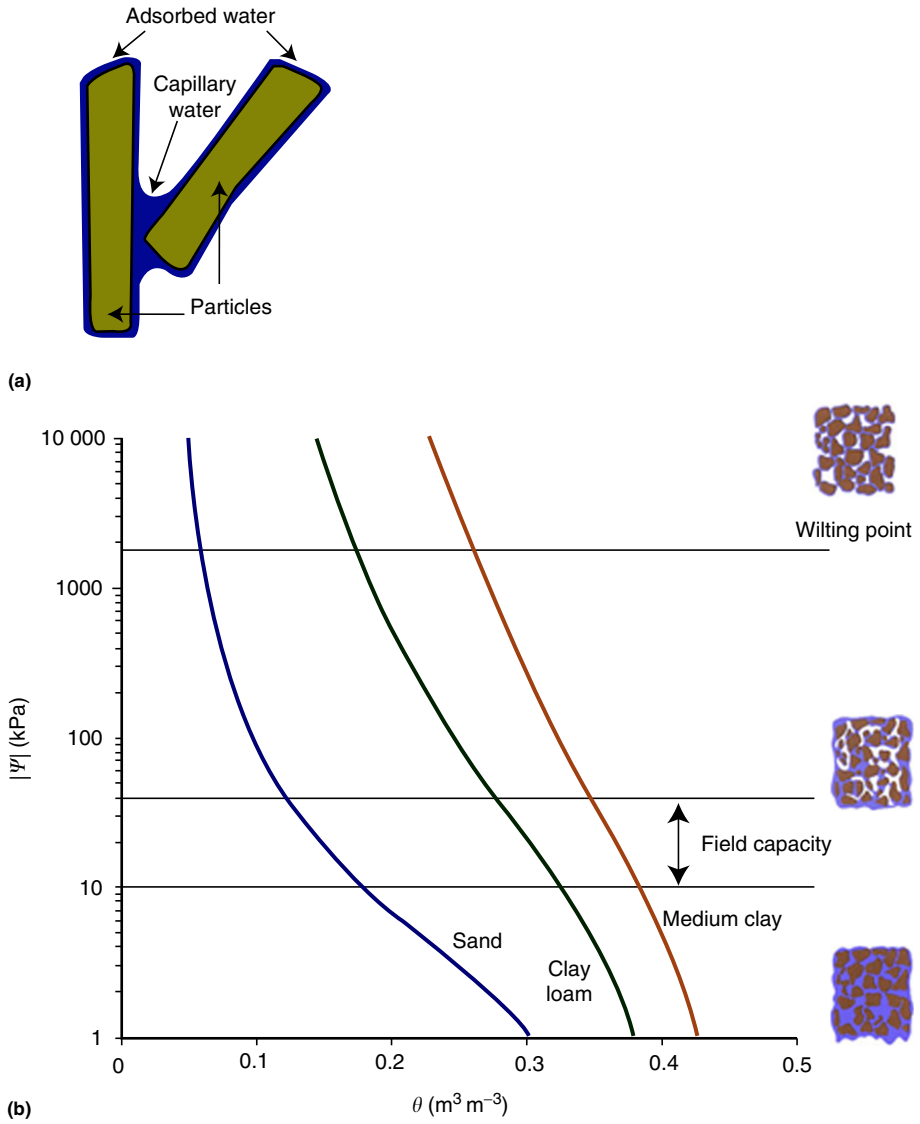

Figure 9 A representation of (a) adsorbed and capillary water and (b) the water retention curve for different soil textures, including water availability.

The total water potential of a soil is expressed as follows:

$$\psi = \psi_m + \psi_g + \psi_p + \psi_s \quad [6]$$

In eqn [6] the osmotic potential (ψ_s), is only measured in soils where there is enough dissolved salts to reduce the free energy of water, i.e., saline soil. In a saturated soil the $\psi_m = 0$. The pressure potential (ψ_g) in most circumstances is negligible and may be considered in relation to the presence of a soil water table, where above that water table ψ_m is negative and below the water table ψ_p is positive.

The relationship between the matric potential and volume of water held in the soil is represented as the water retention curve (Figure 9(b)). When all the pores are full of water the potential is equal to zero and the soil is said to be at saturation. As identified earlier, the FC is achieved when all the pores that freely drain in response to the gravimetric potential being greater than the matric potential have done so, leaving only medium and small pores filled. FC is commonly reported on the soil water curve between the potentials of -10 to -33 kPa, or the amount of water held in a soil after it has been allowed to drain for 2–3 days.

In most cases, once a soil has achieved FC there will be at least 10% air-filled porosity, which is required for healthy plant growth and root development. In Figure 7, the difference in area between the porosity and FC represents the air-filled porosity and for all depths in the four profiles it is greater than 10%. For sandy soils the rate of drainage from saturation to FC occurs faster than for clay soils, meaning that there is the potential for the clayey profiles, such as Callandoon (Figure 7(c)), to experience a number of days where the air-filled porosity is less than optimal. These conditions, often described as waterlogged, can lead to the loss of soil nutrients such as nitrogen. The air-filled porosity of a soil can also

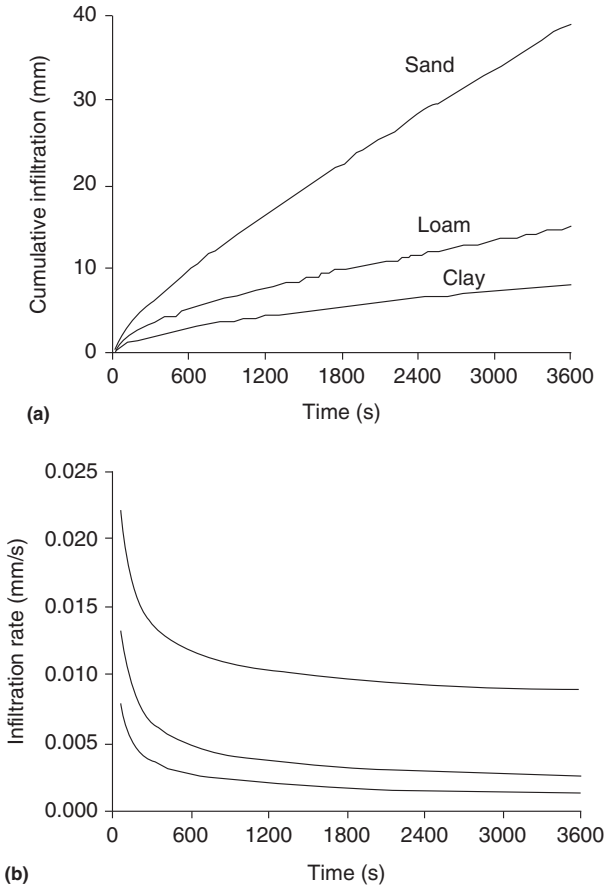

Figure 10 (a) Cumulative infiltration (b) and infiltration rate for sand, loam, and clay-textured soils. Reproduced from Minasny, B., George, B. H., 1999. The measurement of soil hydraulic properties in the field. In: Cattle, S.R., George, B.H. (Eds.), Describing, Analyzing and Managing Our Soil. Sydney, NSW: University of Sydney Publishing, pp. 185–204.

be calculated as follows:

$$\varphi_g = 1 - \left(\frac{\rho}{\rho_s}\right) - \theta \qquad [7]$$

As the soil dries it will become more and more difficult for plants to remove water and eventually there is a point reached where the plant will wilt and cannot recover its turgidity, known as the PWP (**Figures 7** and **10(b)**). The amount of water between the FC and PWP is known as the available water capacity (AWC) and can be expressed as

$$AWC = (\theta_{FC} - \theta_{PWP}) \qquad [8]$$

The unavailable water completes the moisture characteristic curve and this does influence soil that is prone to shrinking and swelling resulting in large cracks during dry periods, which close on wetting affecting the rate of water movement and distribution in the soil. For all practical purposes though the two fixed points that define the plant AWC are paid the most attention.

The estimates of FC and PWP are determined in the laboratory but the upper and lower limits of the AWC can also be determined in the field using the crops that will be grown. This is achieved by monitoring the change in the soil water content from when it is completely saturated until water is no longer available to plants, causing them to permanently wilt and die. Once the soil is saturated the moisture content is monitored until drainage has almost ceased and this is termed the drainage upper limit instead of the FC. Once the crop that is grown shows signs of significant stress the soil water content at this point is taken as the lower limit (LL) and is used instead of the laboratory determined PWP. A detailed description of this procedure can be found in Ratliff *et al.* (1983). The advantage of using this field technique is beyond being soil- and crop-specific; it also takes into account the rooting depth of the plants and the volume of soil that can be explored to extract water. In the case of irrigation, knowing when it is getting more difficult for a plant to extract water is used to schedule irrigation events. This critical limit is identified as the readily available water and this takes into account the amount of water that is adequate for plant physiological function and is termed the deficient available water.

Finally, when meteorologists refer to rainfall and farmers talk about water in the soil or water used for irrigation, they will usually express this as a height (e.g., mm of rainfall). Also, if the rooting depth of the plants that are grown is known this can be used to determine the lower limit to which the plant will explore the soil and where water can potentially be extracted from. Based on this it would be useful to be able to determine the volume of water held in each horizon of the soil as a length, d, and is calculated using the following relationship:

$$d = \theta \times 1000 \times z \qquad [9]$$

where d is the equivalent depth in mm and z is the thickness of the horizon in meters in a meter of soil.

Soil Water Infiltration

The entry of water through the soil surface is called infiltration. How much water enters and the rate of its entry into the soil is determined by the soil texture, its surface condition and the soil porosity (**Figure 10(a)**). The presence of stable soil aggregates on the surface will favor water entry, but if aggregates slake and disperse the liberated soil can block the soil pores reducing the infiltration. The presence of swelling clays in a soil can reduce the infiltration rate as the size of conducting soil pores is reduced. As soil becomes wetter with infiltration the gradient in the ψ_m becomes smaller and gravity becomes the only driving force the rate of infiltration will also reduce (**Figure 10(b)**).

The process of infiltration, once a soil surface is ponded, involves saturation at the soil surface layer of the soil profile, which is called the saturation zone (**Figure 11**). Below this is a zone that has a relatively constant water content that is less than saturation but greater then FC identified as the transmission zone. The initial nonlinearity in the infiltration curve is more pronounced the drier the soil as the ψ_m is the dominant force affecting water movement. At the wetting front the water content decreases rapidly to the initial water content of the soil profile. This decrease in the water content will reduce the overall water flow through the soil. Generally, an infiltration rate of >50 mm h^{-1} will allow water to enter the soil

and avoid excessive ponding, which may lead to runoff and erosion on sloping topographies. Under rainfall ponding may not be achieved and the infiltration is controlled by the rainfall rate and may result in unsaturated flow.

The longer that ponding conditions persists, the deeper the wetting front penetrates into the soil. Once the water supply ceases a process of redistribution of water in the profile takes place. After redistribution, the wetting front will move further into the profile and the redistribution of water stored in the profile moves from the area (A) to area (B) as demonstrated in Figure 11.

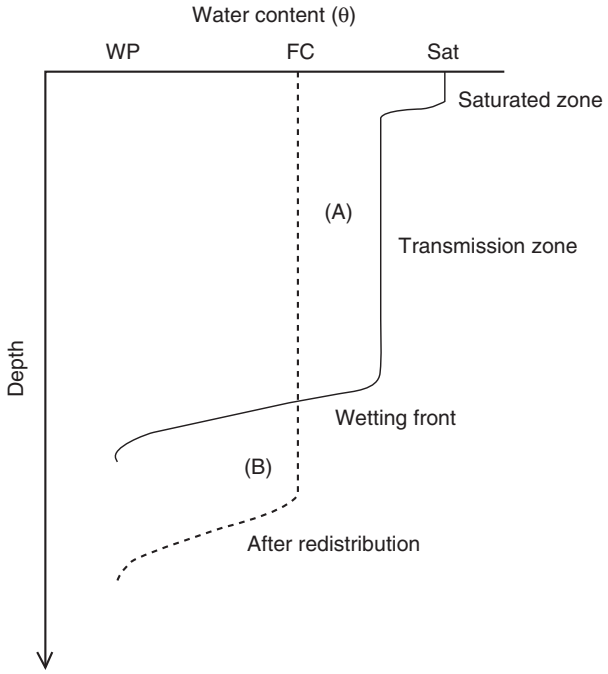

Figure 11 Vertical water infiltration in a soil profile, where Sat is the water content at saturation, FC is the field capacity of the soil, and WP is the wilting point. Reproduced from Minasny, B., George, B.H., 1999. The measurement of soil hydraulic properties in the field. In: Cattle, S. R., George, B.H. (Eds.), Describing, Analyzing and Managing Our Soil. Sydney, NSW: University of Sydney Publishing, pp. 185–204.

This movement of water through the soil is controlled by its hydraulic conductivity (K) and the assessment of the saturated hydraulic conductivity is given in McKenzie and Cresswell (2002).

The hydraulic conductivity of the soil follows Darcy's law, being

$$\frac{Q}{A} = -K\frac{\Delta h_t}{L} \quad [10]$$

where Q is the volumetric flow rate ($m^3\ s^{-1}$), A an area (m^2), K is soil hydraulic conductivity ($m\ s^{-1}$), h_t is the change in hydraulic head or total potential (m) of both matric and gravimetric and L is the flow path length (m). The saturated hydraulic conductivity determines the suitability of a soil for various uses as summarized in Table 4.

For all the soil profiles except Callandoon (Figure 10), the hydraulic conductivity is rapid or greater, and therefore is not limiting in water infiltration. Although the K_s for Callandoon is $<400\ mm\ d^{-1}$ at the surface, resulting in this soil being classed as slow to moderate (Table 4), when this soil dries it forms significant cracks which then allow the water to enter the profile and then infiltrate laterally into the soil. This process is desirable in heavy clay soils with small K_s, especially when irrigation is to be used, and is known as 'wetting from the bottom up.'

The decrease in the K_s for Nowley is due to the significant change in texture. The extremely high K_s for the Pilliga soil (Figure 12) throughout the profile means that is it prone to loss of water through deep drainage and this combined with the small water holding capacity this soil would not be suitable for crop production.

Maintaining a surface condition of the soil that does not impede infiltration is essential to avoid surface runoff (Table 4). The buildup of hydrophobic organic matter, such as waxes, at the soil surface can induce soil water repellency which can reduce water infiltration by an order of magnitude. Generally, severe water repellency is uncommon so it is not a widely spread issue. The subsurface flow of water from higher areas to the base of slopes will contribute to seepage. If the K_s is too large this will enable water to flow below the root zone before it is used by the plant and will contribute to deep drainage, which is a loss of valuable water from the system and

Table 4 Interpretation of saturated hydraulic conductivity in relation to drainage, runoff, and equivalent rainfall intensity

Drainage class	*Interpretation*	*Hydraulic conductivity (mm d^{-1})*	*Type of rainfall*
Extremely slow	Liable to waterlog; land restricted to shallow rooting plants	<8.5	Fine mist to drizzle
Very slow		8.5–30	
Slow	Poor infiltration may lead to overland flow and erosion on slopes	30–120	Slight to moderate rainfall
Moderate		120–480	
Moderate	No problems except on very steep slopes where erosion could occur	480–1500	Downpour to violent rainfall
Moderately rapid		1500–3000	
Rapid	No problems except on very steep slopes where erosion can occur	3000–6000	Violent rainfall
Very rapid		>6000	Extreme rainfall

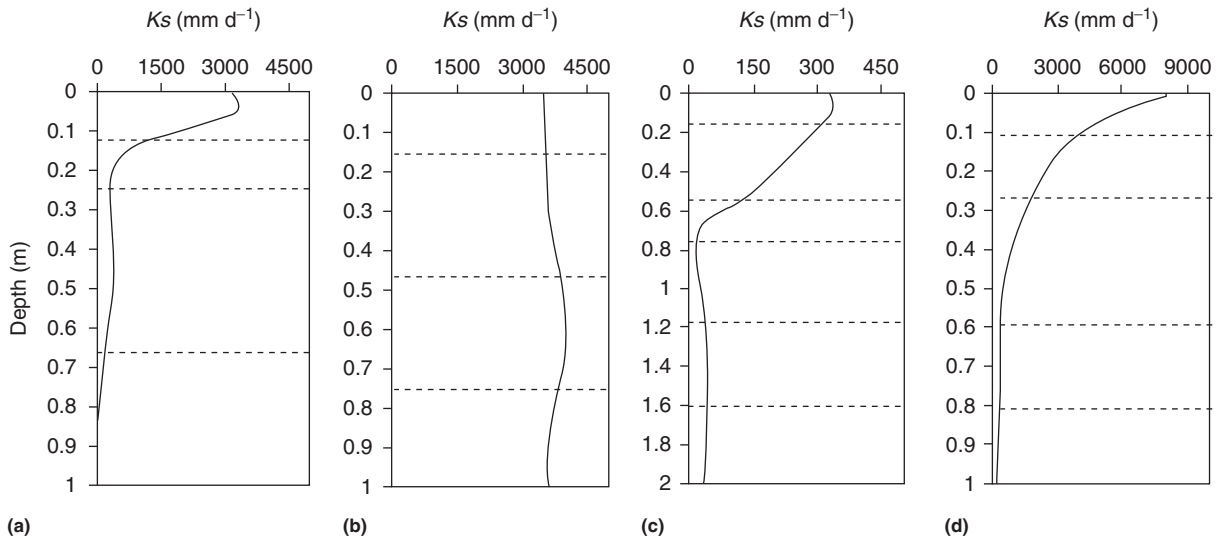

Figure 12 The saturated hydraulic conductivity for the soil profiles. From (a) Nowley, (b) Pilliga, (c) Callandoon, and (d) Toowoomba.

also has the potential to carry unwanted nutrients and other contaminants into the underlying ground waters.

A final account of water is when the area is considered as a discrete unit or catchment. In this case the hydraulic processes are accounted for using the water balance equation as follows:

$$P + I - R = ET + D + \Delta S \qquad [13]$$

The evapotranspiration from the soil–plant system is measured as ET and the responding change in the soil water storage is given as ΔS. The amount of water supplied through precipitation P and irrigation I, as well as, lost through runoff R and drainage D are also accounted for and all these parameters are measured in mm. When ET exceeds P for a period there is a loss of stored water ΔS and a soil water deficit develops. As described in Section Soil Water Storage, this comes from the plant available water and is dependent on the AWC and the rooting depth of the crop being grown.

Soil Strength and the Nonlimiting Water Range

The performance of plants is affected by other soil properties besides the amount of extractable water defined by the available water content (AWC). The ability of roots to enter and explore the soil is affected by the soil's strength. The soil strength is the resistance of the soil to deformation when exposed to shear forces. The shear strength of the soil is affected by the bulk density and its water content. This relationship is demonstrated in Figure 13 and it can be seen that an increase in clay content translates to an increase in the soil resistance, whereas an increase in water content decreases the soil resistance. In the field the soil strength is measured by determining the amount of resisting force when the soil is penetrated using a penetrometer. At FC the soil strength should be <2 MPa to enable root penetration and should not exceed 3 MPa at PWP. If the water content is not known a rule of thumb is that the soil strength should not exceed 2.4 MPa.

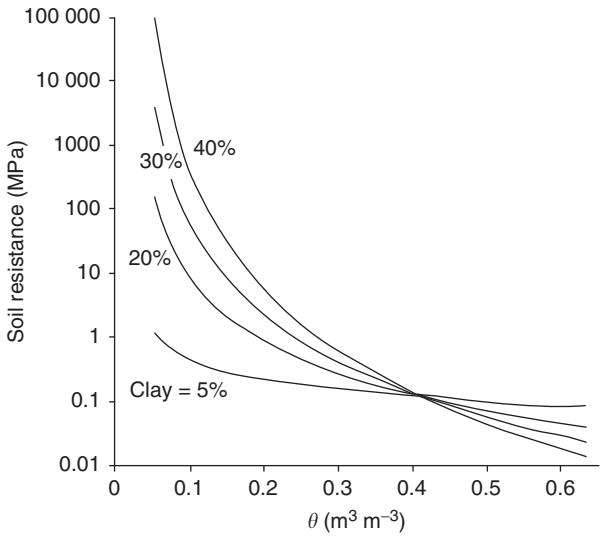

Figure 13 Changes in soil resistance with clay content and moisture content.

For most soil profiles it is expected that the penetration resistance will increase with depth and is affected by the changes in the soil texture, bulk density, and moisture content at the time of sampling. The penetration resistance for the soil profiles in Figure 14 was assessed using the dynamic penetrometer and it can be seen that both Nowley and the Toowoomba soil has a penetration resistance at depth which far exceeds the critical limit commended for plant root development. The dimensions of the cone tip of the penetrometer and its rigidity means that the penetrometer may be forcing its way through the peds in the soil, whereas roots are able to explore the tortuous cracks and pores. The natural planes of weakness resulting in cracks between the peds in the Nowley soil will provide for root development along the surfaces of the peds, and the fine peds developed in the Toowoomba profile will also enable root development (Figure 1). The penetration

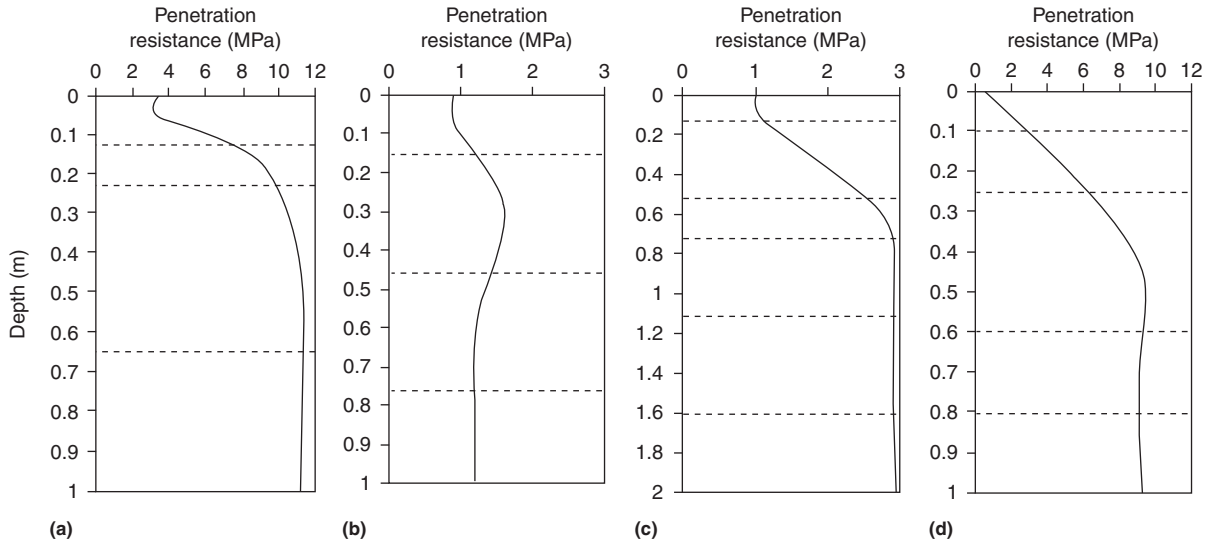

Figure 14 Changes in penetration resistance with depth measured using a dynamic penetrometer for the soil profiles at (a) Nowley, (b) Pilliga, (c) Callandoon, and (d) Toowoomba.

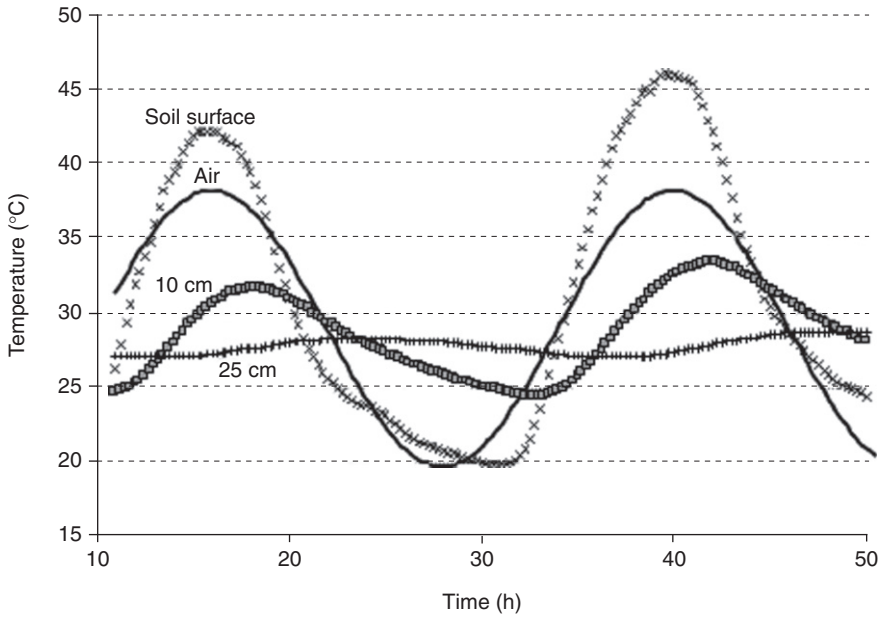

Figure 15 The change in soil temperature from the surface to a depth of 25 cm over a period of 40 h.

resistance for the Pilliga and Callandoon is not as limiting and the uniformly sandy texture in the Pilliga profile is probably responsible for little variation in strength with depth.

Soil Temperature

The main source of energy input to increase the soil temperature is solar radiation. The color of the soil surface, the amount of vegetation, and the slope of the land in relation to the sun all affect the soil temperature changes. The amount of heat a soil can absorb is defined as its thermal capacity and the transfer of the heat through the soil is controlled by its thermal conductance. These two properties moderate how the temperature of the soil varies with depth. This variation is greatest at the soil surface; with depth the variation in soil temperature decreases (Figure 15). It can also be seen that the change in soil temperature with depth over 24 h shows a lag with depth primarily due to the soil's thermal conductivity.

During the day dark colored soil reflects less radiation than light colored soil, but at night dark colored soil will radiate energy faster. The lack of vegetation on the soil surface will not protect the soil surface from solar radiation or insulate the soil from losing heat at night. An increase in moisture content will

also enable the soil to absorb more heat and this is because water has a higher heat capacity. This combination of water content and soil temperature will affect the germination of plants and the development and efficiency of soil roots.

Applying mulch to the soil surface is a process of spreading dead plant material which will reduce the temperature extremes and reduces evaporation at the soil surface. This is because mulch has a lower thermal conductivity, caused by the interlocking air spaces around the mulch material. The mulch will also protect the soil surface from the forces of water during rainfall minimizing the potential disruption of soil aggregates that could block soil pores. The mulch will also minimize the evaporation of water from the soil surface.

Soil Aeration

Soil aeration is critical for optimal functioning of the soil and it is generally governed by three factors: (1) soil porosity, (2) soil water content, and (3) the oxygen demand by soil organisms including microorganisms and plant roots. The lack of O_2 becomes a serious problem when its concentration falls below $0.1\,l\,l^{-1}$, which usually occurs at air-filled porosity $<10\%$. The availability of oxygen in the soil affects the soil redox potential, which in turn affects the forms of compounds of several important elements (e.g., N, S, and Fe) in the soil solution. Consequently, oxygen concentration has influence on the soil chemistry and its pedogenesis. Soils that develop a deep red color in the profile are said to have developed under well-drained conditions, whereas soils that are less well drained develop a yellow to brown color. In a normal toposequence soil at the top of the hill is usually red in color and as you move down the toposequence soil will change through brown into yellow in the lower slopes. At the bottom of the slopes where water accumulates the soil may experience long periods of waterlogging and are usually gray to black in color. These waterlogged soils may show bright yellow or orange stains along pores reflecting that the oxygen levels are fluctuating in the pore phase. In extreme cases, soils may become permanently waterlogged, which is typical in wetlands.

The availability of O_2 regulates the oxidation–reduction states of many plant nutrients. The oxidation–reduction reactions involve a transfer of electron between two species; the species undergoing reduction accepts an electron and the oxidizing species loses an electron. Redox potential (E_h), which is a measure of electrochemical potential or electron availability, is commonly used to predict chemical compounds or processes that regulate nutrient or metal availability in soils. Soil E_h values are generally between -1 and $+1$ V, with values decreasing with decreasing O_2 availability. The common oxidants in soils are O_2, NO_3^-, Mn^{4+} (Mn^{3+}), Fe^{3+}, SO_4^{2-}, and CO_2, whereas the reductants are various organic substrates and reduced forms of inorganic compounds (e.g. H_2O, N_2, Mn^{2+}, Fe^{2+}, H_2S, and CH_4).

In addition to the adverse effects on plant growth and microbial activity, prolonged anaerobic conditions affect the availability, transformation, and degradation of environmentally relevant organic and inorganic compounds.

Clay Minerals and Cation Exchange Capacity

The clay minerals can be broadly grouped into two categories: (1) phyllosilicates (layered aluminosilicates) and (2) nonphyllosilicates; both groups of minerals carry permanent negative or variable charge. Permanent charge in the phyllosilicates originates from the isomorphous substitution in their structure (mainly 2:1 layer minerals). For example, the substitution of Al^{3+} for Si^{4+} in the tetrahedral sheet or the isomorphous substitution of Mg^{2+} for Al^{3+} in the octahedral sheet will result in a net negative charge in the structure. Table 5 lists the phyllosilicates and associated permanent charge with each of the mineral groups. There is a wide range for the CEC values for each clay mineral or mineral group because of the inherent range in the isomorphous substitution, and other crystallographic and chemical properties of the minerals. The classification of the 2:1 phyllosilicates in Table 5 is based on the layer charge per formula unit (i.e., $O_{10}(OH)_2$); this layer charge determines the edaphic soil properties such as CEC, water retention, and transmission.

The variable or pH-dependent charge are primarily associated with hydroxyl groups of phyllosilicates, sesquioxides, allophone–imogolite, and humus; these charges are dependent on the pH and ionic strength of soil solution. Unlike the permanent charge in the clay minerals which is always negative, the variable charge can be negative, zero, or positive depending mainly on the soil pH (Figure 16). There is a characteristic pH for each mineral or humus compound at which the net charge is zero, i.e., positive and negative charges are equal, which is called as the point of zero charge (PZC) (Table 6). Variable charge minerals (and humus) will carry a net negative charge at pH values greater than its PZC value, and a net positive charge at pH values lower than its PZC value. For a soil containing a mixture of variable charge minerals, the PZC value of the soil

Table 5 The layer charge, cation exchange capacity, and specific surface area of phyllosilicates found in soils

Clay mineral/group	*Layer charge (mol per formula unit)*	*Cation exchange capacity ($mmol_c\,kg^{-1}$)*	*Specific surface area ($m^2\,g^{-1}$)*
Kaolinite	~0	30–100	6–54
Illite (clay mica)	0.75–0.90	100–400	30–120
Vermiculite	0.6–0.9	1200–2070	300–500
Smectite	0.2–0.6	800–1350	700–800
Chlorite	Variable	100–400	10–50
Palygorskite–sepiolite	Variable	50–450	800–900
Allophane–imogolite	Variable	100–400	400–1000
Zeolites	Variable	2200–4600	Variable > 1000

Note: In the case of illite, smectite, vermiculite, and chlorite, $O_{10}(OH)_2$ is considered as the formula unit.

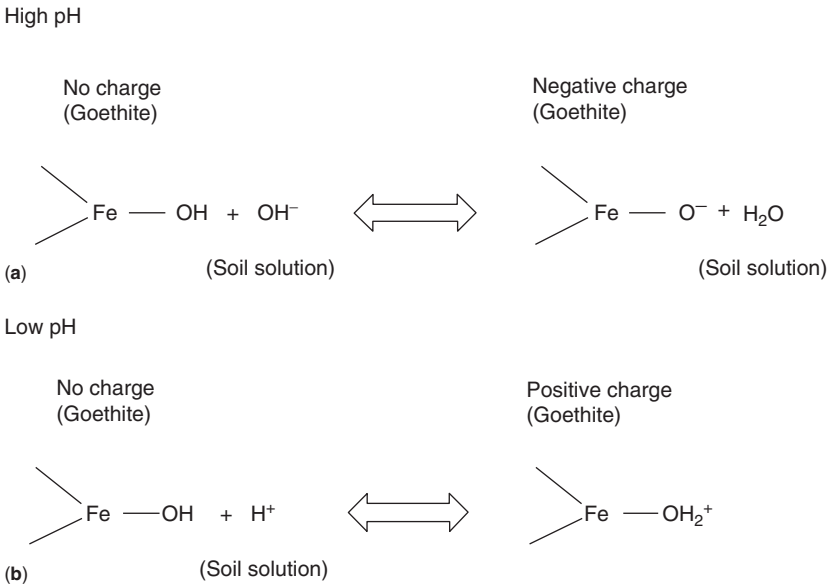

Figure 16 The development of negative and positive charges on the surface of a variable charge mineral, goethite, in response to varying solution pH.

Table 6 Point of zero charge (PZC) values for common soil minerals

Mineral	*PZC*
Kaolinite	4.0–5.0
Goethite, α-FeOOH	7.0–9.0
Hematite, α-Fe_2O_3	8.0–8.5
Gibbsite, α-$Al(OH)_3$	8.0–9.2
Boehmite, α-AlOOH	9.3–10.4
Quartz, SiO_2	2.0–3.0
Manganite, α-MnOOH	~1.8
Birnessite, α-MnO_2	1.5–2.5
Vernadite, δ-MnO_2	~1.5
Calcite, $CaCO_3$	8.0–9.5
Allophane	5.5–6.9

Table 7 Jackson's weathering sequence for minerals in the <5 μm fraction of soils

Weathering stage	*Clay fraction mineralogy*	*Extent of weathering*
1	Halite, gypsum	Less weathered or younger soils
2	Calcite, dolomite	
3	Olivine, pyroxene, amphibole	
4	Biotite, chlorite	
5	Feldspar (plagioclase, orthoclase)	
6	Quartz	
7	Muscovite, illite	Intermediate weathering
8	Vermiculite	
9	Smectite	
10	Kaolinite	Highly weathered soils
11	Aluminum hydroxide (gibbsite)	
12	Fe oxides – goethite, hematite	
13	Ti oxides – rutile, anatase

will depend on the proportion of each of the variable charge component and the interactions among different components.

The negative charge of the clay minerals is an important soil characteristic for retaining essential nutrient cations (e.g., Ca^{2+}, Mg^{2+}, and K^{+}) and in providing buffering capacity to soils. Owing to their small sizes, soil clay minerals have very large specific surface area, which along with surface charge plays an important role in chemical reactions involving nutrient elements and other ions and molecules in soils. Soil clay minerals are also equally important for many physical properties of soil, such as soil moisture retention, solute and water transmission, and soil consistency.

Similar to Goldich's stability series for primary minerals, a weathering sequence has been proposed for the minerals in <5 μm fraction (Table 7). Highly soluble minerals, such as halite, gypsum, and calcite, are least stable and often exist in young soils or soils from arid environments where minimum leaching occurs. Among the phyllosilicates, 2:1 minerals are common in soils at early to intermediate stages of weathering. In highly weathered soils kaolinite, Fe and Al oxides are the most common clay minerals. Among the minerals not considered in Table 9, allophone and imogolite occur in volcanic ash derived soils and Spodsols (Soil Survey Staff, 2010); and palygorskite–sepiolite are common in dry regions in soils formed from sedimentary rocks or lacustrine deposits.

The clay mineral suites of the four soil profiles indicate intermediate to extreme weathering, according to the sequence presented in Table 7. Smectite dominates the clay fraction of Nowley and Callandoon profiles, with small amounts of kaolinite and illite being present in both soils. The clay fraction of Nowley soil also contains hematite, quartz, anatase, and traces of goethite throughout the profile. In contrast with the other two soils, kaolinite is the predominant phyllosilicate in the Pilliga and Toowoomba soils. Hematite is present in a significant amount in the clay fraction of the Toowoomba soil (also indicated by the red color of the soil, Figure 1), along with trace amounts of gibbsite and quartz in the clay fraction. The Pilliga soil also contains small amounts of quartz, anatase, goethite, and hematite in the clay fraction. The clay mineralogy data suggest the highly weathered characteristics of the Toowoomba soil; this is also evident to some extent in the Pilliga soil as well. The alluvially derived Nowley and Callandoon profiles have mixed mineralogy with a dominance of smectite.

Soil Organic Matter

In addition to the inorganic fraction, organic matter is an important constituent of the soil. Typically, surface soil contains between 0.5% and 5.0% organic matter depending on the land use and the climatic conditions. In addition to the climate, other soil-forming factors, i.e., parent material, relief, organism (vegetation), and time, also affect the SOM. Fine-textured soils generally have greater organic matter content than the coarse-textured soils due to: (1) better conditions for plant growth and (2) increased protection of SOM.

SOM consists of a range of C-containing substances that include living (i.e., roots, animals, and microorganisms) and nonliving fractions (freshly to partially decomposed residues of living fraction and well decomposed organic matter – humus). The nonliving fraction of SOM can be broadly classified into three categories: (1) nonhumic compounds ($\sim$20–30% of SOM), (2) humic compounds ($\sim$60–80% of SOM), and (3) black carbon or char (highly variable). The chemical structure and composition of nonhumic substances are well known, and these compounds are cellulose, hemicellulose, proteins, lignins, sugars, starches, polyphenols, waxes, and fats. Humic compounds, however, are dark colored polymeric molecules often with very complex and large structures. Char, or black carbon, in the soil is regarded as a chemically and biologically stable C pool, which can persist for a long period of time (millennia) (Schmidt and Noack, 2000). Limited data suggest that char constitutes a significant fraction of the soil organic C: for example, up to 45% and 60% of the soil organic C pool has been attributed to char C in German and Canadian Chernozems, up to 35% in Australian soils, and up to 18% in native prairie soils in the United States (Baldock and Smernick, 2002; and references there in).

The chemical composition of SOM comprises C (52–58%), O (34–39%), H (3.3–4.8%), and N (3.7–4.1%) (Sparks, 2003). Because C is the major constituent of SOM, traditionally SOM is estimated based on the soil C content, with the assumption that SOM contains 58% C.

There are several direct and indirect beneficial effects of SOM on plant growth. Certain N and P organic compounds can be directly absorbed by higher plants. Additionally, SOM has multiple indirect benefits in terms of chemical, physical, and biological soil properties. The decomposition and mineralization of SOM releases plant available forms of N, P, S, and micronutrients. The specific surface area of SOM is very high and there are a variety of functional groups on its surface. The presence of different types of functional groups (i.e., acidic, basic, and neutral) and the amphoteric nature of the functional groups, SOM provides both cation and anion exchange capacities to the soil. The negative charge in soils is predominantly provided by carboxylic and phenolic groups of SOM accounts for between 20% and 96% of the CEC of surface soils; with the contribution being particularly high ($>$65%) in sandy and highly weathered soils (Sparks, 2003). Thus, SOM serves as a major nutrient reservoir for both the organic and available forms of nutrients. Adsorption of many organic compounds and pesticides largely occur on the SOM and this process is important in preventing the leaching of chemicals into ground water.

Organic matter has a multitude of beneficial effects on soil physical properties including soil aggregation, increased aggregate stability, improved soil infiltration, increased water retention and improved plasticity. The dark color of humic compounds facilitates increased adsorption of solar radiation and increased soil temperature, which is vital for microbiological activity, seed germination and plant growth, particularly in the colder regions. Organic matter is the main carbon source for heterotrophic and larger organisms (e.g., earthworms) in soils.

The global soil C pool (2400 Pg or 10^{15} g) is the largest terrestrial C compared to the C present in vegetation (550 Pg or 10^{15} g) and atmosphere (760 Pg or 10^{15} g) (Batjes, 1996). In recent years, the role of SOM in the global carbon cycle has been highlighted and it has been suggested to be one of the main drivers of increasing CO_2 in the atmosphere and global warming. Human induced perturbations, such as deforestation, fires, artificial drainage, and tillage, have contributed to the increased oxidation of SOM. There is a substantial effort to reverse this process by increasing the soil C pool using a variety of approaches, including increased stabilization of soil carbon, increased addition of SOM, minimizing the mineralization of soil carbon and by adding stable form of carbon, such as biochar, to the soil.

The soil organic content in the surface horizon of all the four soil profiles is much greater than the subsoil horizons. There is an abrupt decline in the organic carbon content of the sandy soil (Pilliga profile), whereas the organic carbon content decreased gradually in the other three soil profiles. Additionally, the three profiles located in the native vegetation contain much higher organic carbon, particularly in the top horizon than the profile from a cultivated field (Callandoon profile).

Cation Exchange Capacity and Exchangeable Cations of the Four Case Study Profiles

The four soils differ considerably in their ability to retain cations, i.e., CEC (Table 8; Figure 17), which can be explained

Table 8 Some chemical properties of the four case study soil profiles

Abbreviation: CEC, cation exchange capacity.

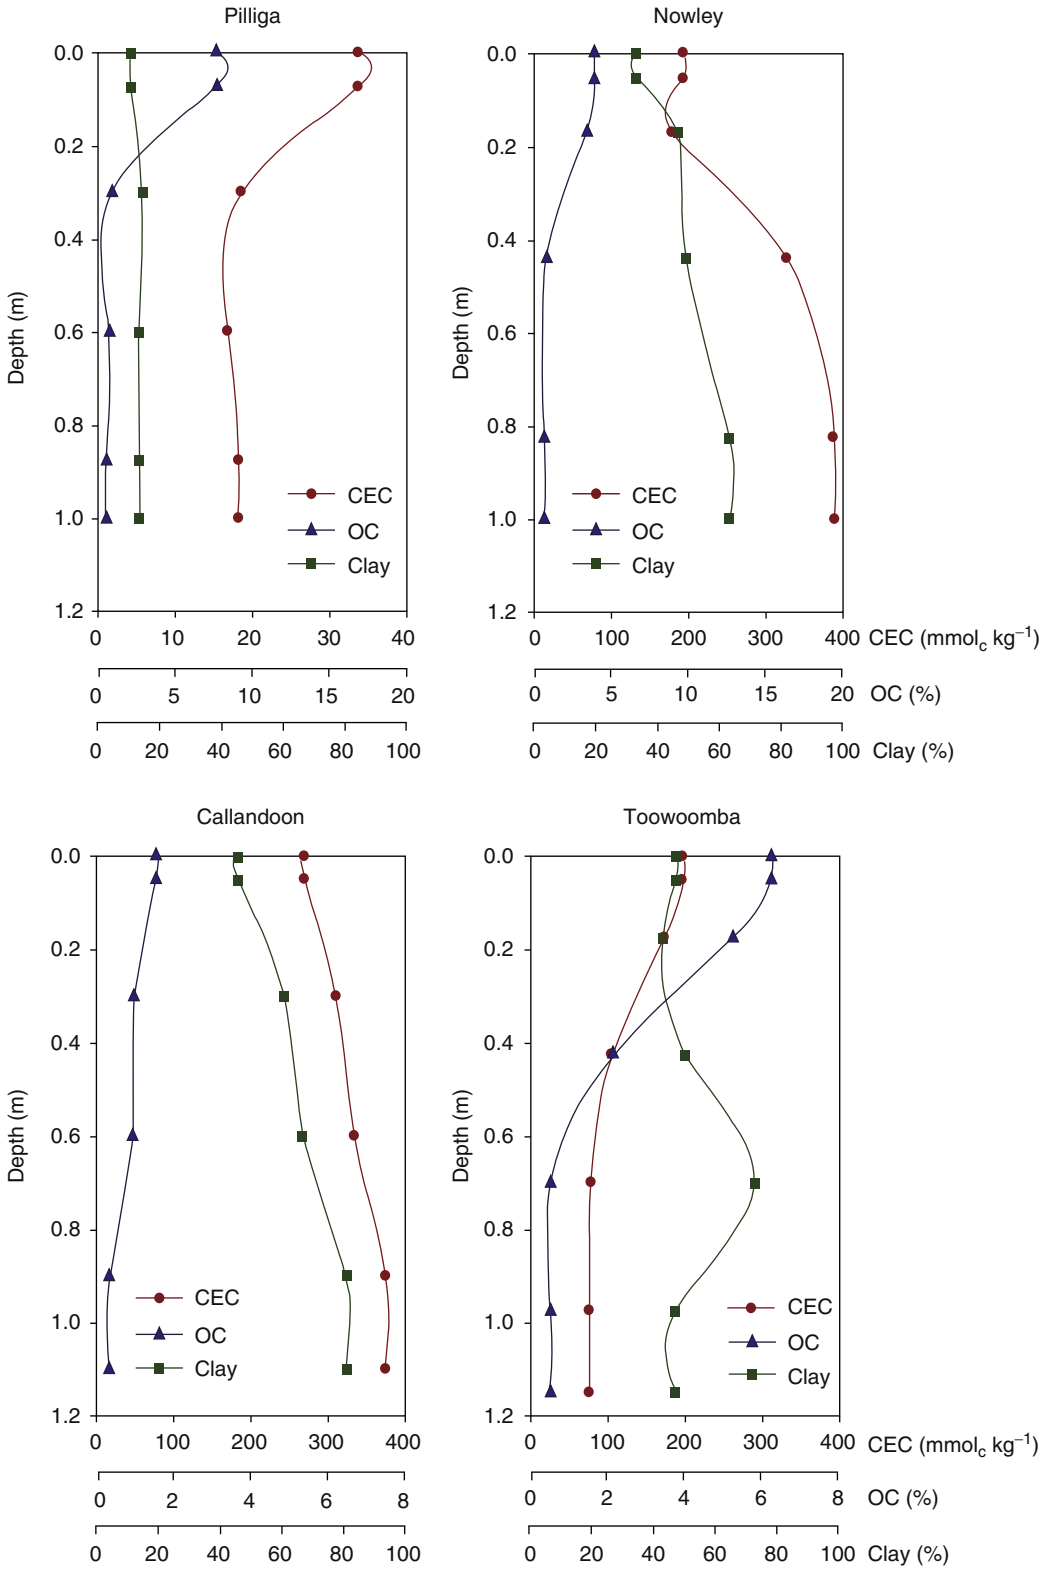

Figure 17 The cation exchange capacity (CEC), organic carbon (OC), and clay contents of the four case study profiles.

on the basis of their organic carbon and clay contents, and the clay mineral composition. The main differences are:

1. Consistently higher CEC for the Callandoon and Nowley soils that is in accordance with their high clay contents and smectite-dominated clay mineral composition.
2. Very low CEC values for the Pilliga profile, which has approximately 10% clay that is comprised predominantly of kaolinite; the contribution of organic carbon to the CEC of the surface soil is obvious with nearly twice the CEC as compared to the subsoil horizons (Table 8).
3. The Toowoomba profile has intermediate CEC values, with the values decreasing with soil depth, which is related to the decreased organic carbon content in the lower parts of the soil profile. Despite the presence of kaolinite and sesquioxides in the clay fraction, the CEC values are reasonable, with a significant contribution from the acidic functional groups of organic carbon in the soil.

Soil Biota

In addition to inorganic and organic soil components, soils are teeming with life that includes both fauna and flora. Based on their size, soil fauna has been classified into: (1) macrofauna (e.g., earthworms, beetles, termites, and ants), (2) mesofauna (e.g., springtales and mites) and (3) microfauna (e.g., nematodes and protozoa). Soil flora includes plant roots and microflora, such as bacteria, fungi, algae, actinomycetes, and very fine root hairs. Soil organisms perform a variety of functions in soils and the activities of flora and fauna in soils are ultimately related with plants being the primary producers of organic molecules and living tissues. (Brady and Weil, 2008). Soil fauna or primary consumers initiate the biochemical decay and mechanical breakdown of plant residues that is followed by complete decomposition by heterotrophic and saprophytic microorganisms. During the mineralization of SOM available forms of nutrients, most notably N, P, and S, are released. In addition to the inorganic transformations of N, S, and P, the availabilities of Fe and Mn in soils are largely controlled by the microbial-driven processes.

Many macro- and mesofauna (e.g., termites, ants, and beetles) redistribute soil solids or make major alterations to it and modulate soil structure in the bioturbation process. Earthworms are well known for their capacity to ingest large masses of soil, to create macropores and to enhance the aggregate stability of soils. The production of organic compounds by soil fauna and flora promotes soil aggregation, enhances aggregate stability, and increases water infiltration.

In agricultural soils, two symbiotic associations, those of legumes with rhizobia and plants with mycorrhizae, are extremely important in maintaining soil fertility. The fixation of atmospheric nitrogen, by the association of bacteria from *Rhizobium* and *Bradyrhizobium* genera with legume roots, represents the major source of N input in many agricultural soils. In the legume/rhizobia association, bacteria use C and nutrients in return for fixed N. The mycorrhizal association is a symbiosis process between the mycorrhizal fungus with a host plant, and in the process fungus derives carbon from the host plant and the plant receives increased inorganic nutrients (particularly P) from the fungus.

Because of their sensitivity to the changes in soil environmental conditions and their role in many key soil processes, microbial indicators (e.g., such as microbial biomass, diversity, and activity) are frequently used as soil quality indicators (Dilly *et al.*, 2006).

pH

Soil pH is a very important property from a plant growth standpoint. It is a measure of hydrogen ion activity in soil solution. Measured in the field or in the laboratory using an electrode or some form of indicator solution or test strip, soil pH is broadly linked to the pH of the parent material, but is often affected by pedological processes such as the leaching of solutes. In soil profiles of humid environments with parent materials containing appreciable concentrations of bases, it is common to observe increasing values of soil pH with depth in the profile due to the leaching of soluble bases. The Nowley profile is a good example of this scenario; the pH values of the four horizons shown, from top to bottom, are 6.1, 7.0, 8.7, and 8.9 (Table 8). The white patches evident in the bottom horizon of this soil are small areas of calcium carbonate or lime, which is a sparingly soluble salt that precipitates in soil, and which confers an alkaline pH to soil. In the Nowley profile, the local rainfall regime has resulted in lime being precipitated at a depth of 70 cm, in a zone of base accumulation.

The importance of soil pH to plant roots is twofold; firstly, there are direct effects, whereby at low soil pH values H^+ and Al^{3+} are common ions in the soil solution and are toxic to some plant roots, and secondly there are indirect effects, where at low or high soil pH values various plant micronutrients become unavailable and other elements (e.g., Al^{3+}) are converted into forms toxic to plant roots. Furthermore, the activity of microbial communities and a range of chemical reactions in soil are also affected by fluctuating pH.

Electrical Conductivity

Soil electrical conductivity (EC) is a critical edaphic property for plant growth. EC is measured in the field or laboratory using an electrode or electromagnetic sensing device, and is greater in soil that is moist, dominated by clay minerals and containing large amounts of soluble salts. Salinity of a soil profile is usually estimated through the measurement of EC of solution extracted from soil–water mixture or soil paste. The presence of soluble salts in a soil is partly linked to the soil's parent material, but is more strongly associated with the climatic regime of the area and in some cases the topographical location of the soil. The application of poor quality water or restricted drainage can also cause soil salinization, which is somewhat evident in the Callandoon profile with EC increasing in the subsoil (Table 8). The importance of salinity to plants is that large concentrations of salts raise the osmotic potential of the soil water, making it more difficult for plant roots to extract water, even if there is much water present in the soil. At very high concentrations, certain cationic (e.g., Na^+) and anionic (e.g., Cl^-) species may also directly interfere with cellular processes in plant roots. The activity of microbial communities and a range of chemical reactions in soil are also

affected by fluctuating EC. Generally, soils with EC of saturation extract > 4 dS m^{-1} are considered saline; however, sensitive crop plants (e.g., tomato) may be adversely affected at EC > 2 dS m^{-1}.

Plant Nutrients

The most important agricultural plant nutrients, nitrogen (N), phosphorus (P), and potassium (K), tend to be present in greatest concentrations in the topsoil horizons. This is due to the cycling of these elements through the rhizosphere, the incorporation of these elements into various organic compounds, and in agricultural soils, the application of fertilizers. Soil parent material is an important determinant of P and K status of the soil, but climate (rainfall) and organisms (N-fixing bacteria) are more important soil-forming factors governing the presence of topsoil N. Some exchangeable cations such as Ca^{2+} and Mg^{2+} are also important plant nutrients. The concentrations of these cations, which are exchanged onto negatively charged surfaces of clay minerals, depend partly on the soil parent material and partly on climatic and topographic processes. Exchangeable cation concentrations are not necessarily greatest in the topsoil horizons of soil profiles, and are sometimes used as diagnostic criteria for soil classification purposes.

Seventeen elements (also called nutrients) that are considered to be essential for crop plants along with their ionic forms utilized by plants are listed in Table 9. Plants take up nutrients in their available forms from soil solution through mass flow or diffusion processes. Plant nutrients in soils exist in various pools including soil solution, exchangeable, specifically adsorbed, mineral structures, chemical compounds and organic matter. At a given time only a small proportion of the total amount of the nutrient in soil is present in the plant available form and a dynamic equilibrium exists between various nutrient pools including the solution form.

Table 9 Essential plant nutrients and their plant available forms

Basic or structural nutrients *Name*	*Symbol*	*Plant available form*
Carbon	C	CO_2 and H_2CO_3
Hydrogen	H	H^+, OH^- and H_2O
Oxygen	O	CO_2
Primary or major nutrients		
Nitrogen	N	NO_3^- and NH_4^+
Phosphorus	P	HPO_4^{2-} and $H_2PO_4^-$
Potassium	K	K^+
Secondary nutrients		
Calcium	Ca	Ca^{2+}
Magnesium	Mg	Mg^{2+}
Sulfur	S	SO_4^{2-}
Micronutrients		
Boron	B	H_3BO_3 and $H_2BO_3^-$
Copper	Cu	Cu^{2+}
Chlorine	Cl	Cl^-
Iron	Fe	Fe^{2+} and Fe^{3+}
Manganese	Mn	Mn^{2+}
Molybdenum	Mo	MoO_4^{2-}
Nickel	Ni	Ni^{2+}
Zinc	Zn	Zn^{2+}

In soils, N mostly occurs in the organic form, which must be mineralized (conversion of organic nitrogen into inorganic form is called as mineralization) before plants can take it up. For all N-fertilizers, the applied and mineralized N ends up in the nitrate (NO_3^-) form, which is very mobile in most soils due to the predominance of the negative charge on soil colloids. Nitrate leaching is a common problem in many agricultural soils and particularly in light textured soils. Highly weathered soils are known to retain NO_3^-ions due to the presence of positive charge on Fe (and Al) oxides at acidic pH of these soils. Soils from the temperate regions, with the dominance of 2:1 phyllosilicates (e.g., smectite and vermiculite), can retain significant amount of ammonium (NH_4^+) ions in the interlayer space of these minerals. The losses of N in gaseous forms are also common under certain conditions, for example, nitric oxide (NO), nitrous oxide (N_2O), and dinitrogen (N_2) in anaerobic soils and ammonia (NH_3) in alkaline soils. Although a significant amount of fertilizer N is applied in most cropping systems, the fixation of atmospheric nitrogen by legume plants still remains the major source of N in many cropping systems throughout the world, particularly in low input agricultural systems.

The availability of P is a common problem in most acidic and alkaline soils due to the precipitation of insoluble compounds (Fe and Al-phosphates in acid soils and Ca phosphates in alkaline soils) or specific adsorption of phosphate ions onto crystalline and amorphous phases of Fe and Al oxides. Unlike nitrate, the available forms of P are immobile due to their chemical interactions with a variety of soil colloids.

Most of the K in soils is present in K-containing primary minerals, i.e., micas and feldspars. Depending on the extent of soil weathering, varying amounts of K minerals are present in different soil types. Temperate soils often contain abundant K-rich minerals and thus may require little or no application of K fertilizers, however, many sandy soils require the application K fertilizers for optimal plant growth. Soils at intermediate to advanced stages of weathering often contain illite (clay-size mica), which can potentially supply K. In many soils that contain clay minerals formed from the weathering of mica, such as vermiculite, the fixation of fertilizer applied K could become a problem in such soils that may be overcome by increasing the fertilizer application rates.

Secondary nutrients (Ca, Mg, and S) are usually present in adequate amounts in less weathered to intermediate weathered soils. Soil minerals, organic matter, and crop residues are all good source of secondary nutrients in soils. In highly weathered acidic soils, lime that is usually added to raise soil pH supplies Ca. Sulfur is also added as an impurity in low-grade fertilizers and through gypsum ($CaSO_4 \cdot 2H_2O$), which is used as an amendment in sodic soils.

Micronutrients, although required in very small amounts by crop plants, can be deficient in certain soil conditions, such as highly weathered acidic soils, sandy soils, highly alkaline soils, or in soils that are used for intensive farming. The cationic form of micronutrients (e.g., Fe, Zn, Cu, and Mn) usually are deficient in alkaline soil pH conditions and the deficiency of anionic form elements (Mo and B) are common in highly acidic to acidic soil conditions. In addition

to this, the availability of most cationic and anionic micronutrients is affected by their strong adsorption reactions to Fe and Al oxides.

Soil testing is done to evaluate the availability of nutrient elements in agricultural soils and to make fertilizer recommendations for the nutrients. Owing to the complex behavior of nutrients, variable chemical reactions of nutrient ions in different soil types, variable nutrient requirements of field crops, the use of different soil tests, and many other environmental and soil factors, it is not possible to suggest the critical deficiency or sufficiency levels for the nutrient elements that are universally applicable.

Conclusions

Soil is a finite resource that develops over a long time span. Despite the resilience and significant buffering capacity of soils, the increased exploitation of soils for food, fiber, and energy production can cause degradation with time and severely affect their productivity. Wind and water erosion, compaction and crusting, acidification, salinization, and loss of organic matter are the common features of degraded agricultural soils. Considering the complexity of soils, a multidisciplinary approach is required to understand the soil degradation processes. Additionally, spatial and temporal variability must be considered in sampling and modeling the processes and their impacts over geographical scales. There is a need for internationally coordinated efforts for a sustainable use of soils in order to protect them from degradation processes (Blaser, 2006). Future research programs should be based on improved understanding of the degradation processes and mechanisms, reliable and intelligent indicators for measuring and monitoring soil quality, and developing appropriate amelioration techniques and decision-making tools for sustainable use of soils.

Glossary

Aggressiveness A comparative measure of the degree of success of a virulent pathogen isolate on a particular host genotype. Aggressiveness is typically measured in terms of reproductive success.

Biotrophic pathogens The fungi, such as rusts and powdery mildews, that depend on healthy, living host tissue for growth and long-term survival. Biotrophs typically have a narrow host range. Biotrophic fungi stand in distinction to necrotrophic fungi that derive nutrition from host cells they have killed. Pathogens that derive their nutrition necrotrophically are often able to survive as saprophytes in the soil or on plant debris in the absence of a living host.

Gene-for-gene or qualitative resistance A resistance that is based on the expression of single genes typically inherited in a simple Mendelian fashion. Gene-for-gene interactions between hosts and pathogens are controlled by pairs of matching genes in hosts (the resistance gene) and pathogens (the avirulence gene) with the occurrence of a resistant reaction being dependent on the presence of both host resistance genes and the corresponding avirulence genes in the pathogen. Such resistance is pathotype specific being effective against some pathotypes and not others. This form of resistance contrasts with quantitative resistance that is typically controlled by several genes and is expressed equally against all pathotypes of a pathogen.

Host jump The range of host species susceptible to infection is broadened as a consequence of novel encounter between a pathogen and previously unexposed host species. Host jumps require no genetic change in either host or pathogen.

Infectivity The ability of the pathogen to cause a susceptible response on a particular host line.

Throughout ecological and evolutionary time, plant diseases have been important in shaping the structure and diversity of individual host species and communities (Burdon *et al.*, 2006). Although famous examples of devastating epidemics and their consequences have come down through time (e.g., the nineteenth century famine in Ireland, instigated by the potato blight fungus), new examples continue to accumulate. Changes in global climatic patterns, major expansion in the range of plant species associated with agricultural production, and greatly increased movement of people and goods between previously ecologically isolated areas, are all generating a complex mix in which different combinations of pathogens and hosts are brought together more frequently. This is leading to a marked increase in epidemics generated either by pre-existing pathogens or by novel pathogens (or pathotypes) that have developed through a variety of means of genetic recombination. This process has become so prevalent and the novel pathogens generated are often so aggressive, that emerging plant diseases now pose one of the greatest threats to the integrity, sustainability, and productivity of many natural and agricultural plant communities (Fisher *et al.*, 2012). However, it is important to recognize that this process is not entirely new. Indeed, the evolutionary history of many fungal groups is littered with evidence of jumps in the host range of individual pathogen species. This is particularly apparent in the rust fungi where many heteroecious rusts alternate between gymnosperm and angiosperm (e.g., *Melampsora pinitorqua* alternating between *Pinus sylvestris* and *Populus tremula*) or angiosperm and angiosperm hosts (e.g., *Puccinia urticae-caricis* alternating between *Urtica dioica* and *Carex* spp.).

What is an emerging disease? Emerging diseases have been defined as "any disease that is currently spreading within host populations." Although evolutionary change in the pathogen is not a necessary prerequisite for the appearance of an emerging disease, the tag 'emerging disease' carries with it the connotation of a change from the current status quo. However, the status quo is not in itself a situation in which disease is nonexistent. Rather in nonagricultural situations, many host–pathogen associations have coevolved over millennia. However, through the interactive effect of within-and-among season climatic variation, and host and pathogen variability, these interactions may display periodic ephemeral increases and decreases in disease occurrence and severity. Similarly, in many agricultural crops, epidemic cycles may occur on a near-annual basis depending on environmental circumstances. Such interactions are not considered here to be examples of emerging diseases – they are fluctuations representative of the 'normal' dynamics of many host–pathogen systems.

In contrast, emerging diseases may arise in a number of ways through:

1. existing well-recognized pathogens 'catching up' with anthropogenically generated changes in the distribution of existing host species, thus appearing in new geographic regions;
2. ecologically based jumps to new, previously unexposed hosts (no previous evolutionary contact);
3. environmental changes leading to increased aggressiveness in the pathogen or susceptibility in the host, or an expansion of the pathogen's range into parts of its host range from which it was previously excluded; or
4. genetic change leading to an alteration in the host range or infectivity of an existing pathogen species (novel pathogen genotype or species).

The nature of the first two of these mechanisms – potentially simple changes in the ecology of individual pathogens – reflect the way in which anthropogenic changes in many parts of the world have greatly increased the opportunity for long-distance dispersal with its attendant range of new opportunities. Before the advent of increasingly rapid and intense global transport, the flora of whole continent was essentially protected from encounters with exotic pathogens by isolation. Elements of the collapse of 'protection through isolation' can be seen in the spread of human diseases like plague in Europe in the fourteenth century and subsequently in the transmission of diseases from America to Europe and from Europe to the Pacific in subsequent centuries. This increased opportunity for pathogens and naive hosts to come into close contact is a common feature underlying the emergence of many animal, plant, and human diseases. Environmental changes leading to altered host–pathogen interactions are also heavily associated with anthropogenic activities ranging from the consequences of changed nutrient deposition from uncontrolled industrial emissions to changes occurring as a consequence of the local and regional effects of global climate change. Finally, changes in the ecology of individual pathogens and their distribution increase the possibility of juxtapositioning of previously separate entities and hence significantly increase opportunities for genetic recombination.

Ecological Changes in Distribution Causing Emerging Diseases

Pathogens 'Catching Up' with Anthropogenic-Generated Changes in the Distribution of Their Hosts

Classic examples of this class of emerging diseases come from agricultural situations where, over the centuries, crop species have been introduced and grown (often over large areas) in regions far from the original center of diversity of the crop and its coevolved pathogens. Over time, selection for traits other than disease resistance, combined with agronomic practices that favor pathogen increase (high nutrition and large, dense, and genetically uniform stands), make the crop particularly vulnerable to attack. Examples of these situations are found in agricultural (e.g., the Irish potato famine of the 1840s driven by the appearance of *Phytophthora infestans* and the first appearance of stripe rust of wheat caused by *Puccinia striiformis* in Australia in 1979), horticultural (e.g., the collapse of the coffee industry in Ceylon in the nineteenth century due to the impact of coffee rust *Hemileia vastatrix*), and forestry (the worldwide spread of *Dothistroma* needle blight on *Pinus radiata*) plantings. However, once host and pathogen have been reunited for some time and breeding efforts have begun to deploy genetic approaches to control, differentiating between subsequent periodic failings of resistance deployment strategies and whether it is appropriate to confer the status of a 'new emerging disease' is questionable. As identified earlier, when a pathogen has been present for some time and causes periodic epidemics, the status of emerging disease should perhaps be restricted to special circumstances where the threat is broad ranging. An appropriate example of the latter is seen in the threat facing global wheat production through the appearance and spread of a novel pathotype [Ug99] of *Puccinia graminis* f.sp. *tritici* from its area of origin (Uganda) through the Rift Valley to the Yemen and into central Asia (Singh *et al.*, 2011). This pathotype (and its descendants) are of particular concern because their unique combination of virulence genes renders more than 90% of the world's wheat cultivars and breeding materials susceptible to attack.

A further situation involving pathogens reconnecting with established host species is seen in invasive plant species and poses the question of whether pathogens native to an invasive host that later catch up with the invader in its new area, should be regarded as new or emerging diseases, and if so, after how long a time of separation? Two scenarios occur under this rubric: (1) the reuniting of pathogen and host occurs as a result of accidental introduction or natural spread of the pathogen or (2) as a consequence of deliberate attempts to control invasive host species that have typically spread as weeds associated with agricultural activities (biological control programs). An example of the accidental reunification of pathogen and host is seen in *Impatiens parviflora* from Central Asia and the Himalayas, which after its escape from botanical gardens in Europe in 1837, gradually became a dominant species of nutrient-rich forests in Europe. Approximately 80 years later, its native rust pathogen, *Puccinia komarovii*, appeared in these populations causing sufficient damage as to affect host demography albeit not host expansion.

Programs to control invasive plant species through the deliberate release of pathogens collected from their native range provide many examples of explosive epidemic increase with significant impacts on the targeted host species, for example, *Maravalia cryptostegiae*, *Uromycladium tepperianum*, *Puccinia chondrillina*, *Colletotrichum gloeosporioides*, and *Entyloma ageratinae* attacking *Cryptostegia grandiflora* (Australia), *Acacia saligna* (South Africa), *Chondrilla juncea* (Australia), *Miconia calvescens* (Tahiti), and *Ageratina riparia* (New Zealand), respectively (Vogler and Lindsay, 2002; Wood and Morris, 2007; Cullen, 2012; Meyer *et al.*, 2008; Barton *et al.*, 2007). However, the patchy track record of biological control programs emphasizes the inherent unpredictability of pathogen–host interactions and the very strong likelihood that far more dispersal events occur than are ultimately successful.

Jumps to New, Previously Unexposed Hosts

Some of the best known and longstanding examples of emerging plant diseases are the ones in which existing pathogens have been transported to an environment from which they were previously excluded (nearly always by distance from source populations) and in that new environment have come in contact with plant species that lack resistance. In this scenario, there is no evidence of evolutionary change in the aggressiveness or infectivity of the pathogen.

In some instances, the new hosts may be close taxonomic relatives of existing host(s) (e.g., *Cryphonectria parasitica* moving from Asian members of the genus *Castanea* to American chestnut *Castanea dentata*), whereas in others, relationships may be somewhat more variable and distant. A particularly good example of this latter situation is currently unfolding in Australia, where, following the initial identification of *Puccinia*

psidii on *Agonis flexuosa* in 2010, the pathogen's Australian host range has broadened to include more than 130 plant species in a diverse range of 33 genera including *Eucalyptus, Callistemon*, and *Melaleuca* of the Myrtaceae (**Table 1**; Carnegie and Lidbetter, 2012). Given that the pathogen's natural host range in South America involves various members of the same family, it would appear that the Australian host range is reflective of old Gondwanan connections between the flora of these two southern continents.

Typically, the establishment of new host–pathogen associations results from accidental or deliberate movement of the pathogen by humans. However, this is not the case always, and the unforeseen consequences of other activities may create bridges allowing the natural spread of pathogens from their endemic home to new areas. Thus, the relatively recent natural migration of *Melampsoridium hiratsukanum* from Far East to Europe and its appearance on gray alder in northern Europe has been attributed to the closing of a natural gap in the distribution of Siberian and European larches (the alternate host) in eastern Europe by foresters over the past few centuries.

Although examples of host jumps are frequently associated with movement of pathogens into new environments, this is not always the case. Indeed, there are many examples in the literature of exotic stands of important forestry species being attacked by pathogens that naturally occur on related native species. Thus, in Brazil, plantations of *Eucalyptus* species have been severely and repeatedly attacked by *Puccinia psidii*, a rust native to South America, where it has evolved with a number of Myrtaceous species including guava. In South Africa, the native species *Syzygium cordatum* is host to a number of canker and dieback pathogens in the Botryosphaeriaceae that are pathogenic on *Eucalyptus* species; while a range of *Mycosphaerella* species unknown on *Eucalyptus* in Australia cause damage to plantations in Vietnam. Similarly, in Europe, extensive plantations of North American pines have seen host jumps from native pathogens. In the nineteenth century, *Pinus strobus* stands were severely damaged by *Cronartium ribicola*, native to the Eurasian *Pinus cembra*, and more recently large-scale plantations of *P. contorta* in northern Sweden have been damaged by *Gremmeniella abietina*, a pathogen of native conifers.

The importance placed on newly emerging diseases is clearly influenced by their impact. Hence, although *Puccinia malvacearum*, native to Chile, has successfully spread throughout the globe, attacking a broad array of species in the Malvaceae, it is regarded as little more than an oddity as its hosts are neither economically nor ecologically important nor apparently much affected by the disease. A similar case is found in the Australian species *Puccinia lagenophorae* that is now extremely widespread and occurs at high frequency through much of the range of *Senecio vulgaris* in Europe, where although it can have an impact on seed production, it has no apparent lasting impact on host numbers or distribution. Unfortunately, for other introduced emerging pathogens, this is not the case – as is attested to by the dramatic attention-grabbing headlines that periodically occur in both the scientific literature and the popular press. Thus, epidemics of *Fusarium circinatum* (pitch canker) are having a major impact on a number of pine species in California with the potential for >80% of native *Pinus radiata* stands to be destroyed. Elsewhere, its appearance following spread from its putative origin in Mexico or by secondary spread from other infected areas poses a potential threat to economically important pine-based forestry industries in South Africa, Chile, and parts of Europe.

Similarly, *Phytophthora ramorum* (of probable Asian origin) is having a major ecological and economic impact in California, Europe, and the United Kingdom. In California, this invasive species first came to prominence as a consequence of its devastating effects on Californian oak woodlands, where it shows little sign of abating (Cobb *et al.*, 2012) as the tolerance of bay laurel has increased its impact on highly susceptible live oaks and tanoaks. In Europe, the spread of the same pathogen introduced independently from its home range, and although detected on a range of species, shows limited signs to establish in more natural vegetation. Instead, its persistence seems to depend on plantation of infected ornamental shrubs (*Rhododendron* and *Viburnum*). A recent extension of its host range in the UK to include plantations of Japanese larch (*Larix kaempferi*; Webber *et al.*, 2010) – the first time it has occurred on a commercially important conifer – has precipitated a major felling program in an attempt to reduce spread and impose a degree of control. These epidemics are at a relatively early phase and must be expected to continue at high amplitudes until constrained by the pathogen's environmental envelope or by significant reduction in the frequency and density of highly susceptible host individuals.

In the case of *F. circinatum* and *P. ramorum*, reaching a point on the evolutionary trajectory of these newly established host–pathogen associations at which a new ecological balance is established will be a very long-term process. However, more generally, the speed at which such a balance occurs will be host–pathogen combination, and possibly environment, specific. For short-lived species, an ecological, if not genetic, balance may be attained within decades. Successful biological control events that reduce host density and population sizes significantly provide examples here (e.g., the control of *Chondrilla juncea* with *Puccinia chondrillina* in Australia; Cullen, 2012). For long-lived host species, however, this process could take millennia (note, for example, the continuing major epidemic of white pine blister rust [*Pinus* spp. – *Cronartium ribicola*] in the western United States, even though major genes for resistance occurs in some host populations). However, for pathogens with broad host ranges, epidemics may not stop until the susceptible hosts have become extinct.

The different ecological trajectories hitherto shown by *Phytophthora ramorum* in southwestern United States and in Europe further highlight the difficulties involved in forecasting the future dynamics of new host–pathogen associations. In the United States, it is a devastating epidemic drastically altering species composition and dynamics of naive communities and in Europe, it is a destructive pathogen, although seemingly more dependent on trade with infected plant material from plant nurseries and garden centers and with limited effects on native communities. *Phytophthora cinnamomi*, also of probable Asian origin, provides another example. Since the middle of the twentieth century, it has transformed heathlands in southwestern Australia, although its frequent presence in

Table 1 Some examples of past, present, and potential future emerging plant diseases. Note that inclusion in any one category does not exclude the possibility that the disease is still a major problem or may yet migrate to currently disease-free areas

Species	*Hosts attacked*	*Origin*	*New environment*	*Impact*
Past emerging diseases				
Puccinia malvacearum	Wide host range on Malvaceae	Chile	Global	None
Erysiphe alphitoides	Wide host range including Fagaceae, Hippocastanaceae, and Anacardiaceae	First observed in Portugal	Nearly circum-global	Affects regeneration of deciduous *Quercus* spp. in Europe
Phytophthora cinnamomi	Wide host range including Proteaceae, Epacridaceae, and Myrtaceae	Possibly Asia	Western Australia	Major community changes due to loss of multiple species. Limited effects on other continents.
Ophiostoma ulmi	*Ulmus* spp.	East Asia	Europe and North America	Major impact, particularly on ornamental trees. Now replaced by *O. novo-ulmi* (see below under 'Newly emerging diseases').
Uncinula necator	*Vitis vinifera*	North America	Global	Earlier devastating epidemics (in Europe)
Sphaerotheca mors-uvae	*Ribes* spp. above all *R. grossularia* and *R. nigrum*	North America or/and Russia	Europe	Devastating damage on *R. grossularia* (past), now increasingly *R. nigrum*
Cryphonectria parasitica	*Castanea dentata*	East Asia	Eastern USA	Major community changes associated with loss of community dominant
Labyrinthula zosterae	*Zostera marina*	North Atlantic coasts	North Atlantic coasts	Extensive dieback of *Zostera* meadows, slow recover, and dramatic declines among waterfowl, particularly *Branta bernicola*
Newly emerging diseases				
Ophiostoma novo-ulmi	*Ulmus* spp.	Hybrid origin between one European and one North American strain, both originating from Asia, which met in Europe	Europe and western Asia (aggressive hybrid) North America	Major threat to elm forests and ornamental trees
Phytophthora ramorum	*Quercus* spp.	East Asia?	California, Oregon;	Devastating on dominant trees and strong effects on juvenile survival (North America)
	Larix kaempferi Various ornamentals		Western Europe	Extensive stand mortality planted larches (UK)
Discula destructiva	*Cornus florida*	?	North America	Devastation of dominant understorey shrub of many NE American temperate forests
Cronartium ribicola	5-needled pines	Asia and eastern Europe	North America	Major effect on dominant white pines and associated with impact on forestry
Puccinia lagenophorae	*Senecio vulgaris*	Australia	Western Europe	Widespread incidence on *S. vulgaris* in northwestern Europe; little apparent population impact

Puccinia komarovii	*Impatiens parviflora*	Central Asia	Europe	Widespread incidence on *I. parviflora* throughout Europe. No visible effect on host expansion
Gremmeniella abietina (European race)	*Pinus resinosa*	Europe	Eastern North America	Devastating epidemics on *Pinus resinosa*
Puccinia psidii	Wide host range in Myrtaceae including many Eucalyptus species	South America	Australia Hawaii	Potentially devastating to wide range of forest communities in Australia
Phytophthora alni	*Alnus* spp.	Europe ssp. alni of hybrid origin	Europe	Major effect resulting in tree dieback, particularly along slow-flowing watercourses
Fusarium torreyae	*Torreya taxifolia*	?	Florida, Georgia	Drastic population reduction of earlier common species, now critically endangered
Ceratocystis fagacearum	*Fagus* spp.	?	Eastern North America	Major community changes associated with loss of community dominant
Phytophthora austrocedrae	*Austrocedrus chilensis*	?	Patagonia	Major threat to *A. chilensis* and temperate naive forests at the Andean foothills as plantation of exotics are used to prevent disease spread
Future threatening diseases				
Erysiphe flexuosa	*Aesculus* spp.	North America	Europe	Potential threat to native *A. hippocastanum* on the Balkan peninsula
Dasyscypha willkommii	*Larix decidua*	Europe	Europe	Potential threat to high-altitude forests in the Alps
Hymenoscyphus pseudoalbidus (anamorph *Chalara fraxinea*)	*Fraxinus excelsior*	?	Northern Europe	First documented from Poland in 2000, now rapidly expanding, causing extensive host dieback and threatening the host
Heterobasidion irregulare	*Pinus pinea*	North America	Southern Europe	Established and now expanding within a small area in Italy, potential threat to Mediterranean pine and oak forests
Phytophthora lateralis	*Chamaecyparis lawsoniana*	East Asia	North America	Potential threat to native *C. lawsoniana* populations, also expanding on ornamentals on other continents

European and North American soils has not been linked to any epidemics. An alternative explanation is of course that past epidemics resulting in regime shifts and loss of susceptible species have faded out a long time ago.

Environmental Change Causing Emerging Diseases

Season-to-season variation in environmental parameters like rainfall and temperature are well known to drive differences in the incidence and severity of disease epidemics in host–pathogen associations. However, with patterns of precipitation and temperature widely predicted to change in current models of future climate, are there likely to be further increases in the incidence of novel disease problems? This question has been the focus of a growing number of studies in recent years, although a significant problem is to discriminate between epidemics due to more extreme although regularly occurring weather fluctuations (cf. the potato blight famine in Ireland) and long-term climatic trends.

Environmental change has the potential to affect the incidence of emerging diseases through (1) range expansion of existing currently exotic pathogenic fungi or (2) changes affecting the growth, development, or dispersal of native pathogens. There are a range of reasons to believe that range expansion of existing pathogenic fungi or their hosts into new areas will lead to significant and persistent disease epidemics. Ample evidence is provided by the long use of foreign provenances in Swedish and Finnish silviculture where planting of maladapted *Pinus sylvestris* provenances have repeatedly induced severe epidemics of major endemic pathogens (e.g., *Gremmeniella abietina, Phacidium infestans and Melampsora pinitorqua*). A case, where climate change may drive shifts in distribution boundaries to include previously unchallenged and susceptible host populations may become apparent in the European Alps, where high-altitude provenances of *Larix decidua* are unable to survive forestry cultivation at lower levels due to epidemics of *Lachnellula willkommii* (*Dasyscypha w.*) – a canker that under the harsh climate prevailing at high elevations only persists as a saprophyte on fallen twigs (Gaumann, 1950).

However, the effects of climate change are unpredictable and can lead to opposite effects in different areas. For example, warming conditions may result in reduced snow cover in some areas and increased snow pack in others. These differences – essentially different sides of the same coin – may then induce what essentially appear to be major disease outbreaks in some circumstances and significant declines in others. Thus, although reductions in snow cover (depth and persistence) will reduce the impact of endemic snow blight fungi like *Phacidium infestans* – in European boreal forest on *Pinus sylvestris* and in the European Alps on *Pinus cembra* – in other areas snow cover has increased, resulting in significant outbreaks of the parasitic fungus *Arwidssonia empetri* on the dwarf shrub *Empetrum hermaphroditum* – a dominant species of boreal, alpine, and arctic heaths (Olofsson *et al.*, 2011).

Another potential driver for new diseases is the radical change in the global nitrogen cycle which has resulted in accelerating eutrophication of large areas of Europe, eastern and southwestern North America, parts of South America, and East and South Asia, with consequent dramatic impacts on biota. Whether these changes are directly attributable to nutrient changes or are indirectly through changes in the activity of fungal pathogens has rarely been studied for natural communities. However, for nutrient-limited systems, that is the major part of the earth's terrestrial and aquatic biota, increased nutrient availability is more likely to promote both pathogen growth and reproduction. For a number of host–pathogen systems, increased concentrations of foliar nitrogen will favor disease, and rapid responses of increased disease severity among biotrophic and necrotrophic fungal pathogens have been demonstrated both in agricultural as well as natural settings.

Whether disease epidemics are due to a new invader or due to an earlier extant, although benign, endemic population may be difficult to assess due to lack of historical records. For example, during recent decades, forest diebacks have been frequently reported from Europe. First they were claimed to be the result of acidifying air pollution, later increasingly attributed to more extreme weather events or new diseases. Two cases that have attracted much recent attention are observed declines of beech and oak. Recent studies have shown that these declines were caused by several *Phytophthora* species – normally persisting as benign saprotrophic fine-root pathogens – that were favored by periods of high precipitation while the subsequent decline followed periods of protracted drought that hampered annual fine-root formation. Thus, unusual, although not extreme, variations in weather may have far-reaching effects for the reciprocal interaction between the involved partners and it is only in recent years that pieces of these often hidden interactions have been understood.

Disease outbreaks may attract public attention and it is often tempting to interpret observed epidemics as due to climate change or increased eutrophication. However, of key importance for understanding disease dynamics is to never forget the fundamental role of density dependence for disease dynamics. Changed land use, particularly the abandonment of centuries-long histories of livestock grazing, scything, and sampling of fire wood, has over large areas resulted in successional change, including shrubification and closed tree canopies. In such cases, disease outbreaks track pulses in host regeneration. Secondary succession of earlier farmland may also result in increased contacts between alternating hosts as is the case for the present outbreak of *Cronartium flaccidum* on *Pinus sylvestris* in northern Sweden and Finland, where the alternate host *Melampyrum sylvaticum* occurs in abundance on abandoned meadows.

More broadly, the environmental consequences of changing temperature and precipitation regimes, nitrogen loads, and altered land use as well as their interaction will, as mentioned above, have different, even opposing, impacts on different fungal pathogens. For some, little if any change in incidence or severity will be apparent; in other cases, however, such changes will alter the environmental envelope of individual species sufficiently to lead to an increase in activity (more frequent and severe epidemics even including regime shifts), whereas in other cases, the reverse is more likely to be the case.

Genetic Change in Pathogens Causing Emerging Diseases

Notwithstanding the importance of changes in host or pathogen distribution, or of environmental change, genetic changes in pathogens that result in alterations in host range, infectivity or aggressiveness play a very important part in the origin of many highly damaging emerging plant diseases. Such changes may occur through (1) simple single-gene mutations; (2) sexual recombination with closely related species; or (3) horizontal gene transfer (somatic hybridization) with or without subsequent parasexual reassortment.

The simplest of genetic changes that can lead to major epidemics are those typically seen in small grain cereal crops where monocultures of the one resistance genotype are often grown over very large areas, thereby imposing very strong selection pressures on the existing pathogen population in favor of novel genotypes with matching infectivity. Frequently, these changes occur through simple stepwise mutations involving one or two virulence genes as was the case when Australian triticales (wheat × rye crosses) protected from wheat stem rust attack by the resistance gene *Sr27* were rendered vulnerable following the appearance of a newly virulent pathotype of *Puccinia graminis* (McIntosh *et al.*, 1983). The emergence of the Ug99 strain of *P. graminis* and the threat it poses to wheat production over much of the globe is an excellent example of even relative simple genetic changes leading to the appearance of a major threatening disease.

The process of host-imposed selection is a natural part of all wild host–pathogen systems and is particularly apparent in associations in which gene-for-gene type interactions occur. However, although such selection leads to changes in the structure of wild pathogen populations, in those circumstances, the often complex resistance structure of wild host populations leads to epidemic outbreaks that are strictly limited in both time and space (Burdon and Thrall, 1999). There are no known cases where a simple single mutation increase in virulence in a fungal plant pathogen has been responsible for major disease epidemics in nonagricultural systems.

However, significant genetic change that gives rise to the emergence of new and devastating diseases does occur in wild pathogen associations. The primary mechanism for this is through hybridization. Hybridization between related organisms giving rise to a new taxon is increasingly recognized as a major evolutionary force in changing the adaptability of invasive plants and has been long identified as a major factor driving recurrent global human influenza epidemics. Fungi are no different in their capability to recombine, with hybridization occurring through two distinct routes – sexual recombination between closely related species or through horizontal gene transfer (somatic hybridization). In somatic hybridization events, genetic exchange occurring via anastomosis of vegetative hyphae is viewed as the most likely mechanism, although precisely how exchange occurs is still in question as direct observation of the process has rarely occurred. Exchange may result in transfer of whole nuclei, individual chromosomes, or of components of the cell's cytoplasm including plasmids and viruses. Where whole nuclei are exchanged, diploidization, recombination, and subsequent haploidization (parasexual recombination) may or may not subsequently occur (Burdon and Silk, 1997).

Regardless of the actual mechanism, the use of molecular technologies has shown that hybridization between different pathogen isolates, formae speciales, and species is much more common than previously thought and plays a significant role in the origin of several of the more important emerging diseases of agriculture, forestry, and natural systems. Somatic recombination between highly specialized taxon groups like the rusts has been detected between different formae speciales (*Puccinia graminis* f.sp. *tritici* and *P. graminis* f.sp. *secalis* causing stem rust of wheat and rye, respectively; Burdon *et al.*, 1981) or species (*Melampsora larici-populina* and *M. medusa* causing leaf rust of poplar; Spiers and Hopcroft, 1994). Of broader concern are instances of hybridization involving genera housing individual taxa with wide host ranges or pathogens of important dominant species. Probably the best example of the consequences of such events is found in the complex changes that have occurred as two pandemics of Dutch elm disease, the first caused by *Ophiostoma ulmi* and a subsequent epidemic caused by *O. novo-ulmi*, which swept across much of Asia, Europe, and North America during the twentieth century. These epidemics, and the continuing evolutionary changes occurring in *O. novo-ulmi sensu lato* as a consequence of horizontal gene flow, provide examples of an emerging disease that had its origin in the ecological consequences of geographic spread into naive populations but which has subsequently continued to rage as a result of evolutionary changes made possible by the resultant intimate juxtapositioning of taxa that were previously allopatric in distribution (Brasier and Kirk, 2010).

A well-documented example of the emergence of a new pathogen of a staple crop is seen in the emergence of *Pyrenophora tritici-repentis*, the causal agent of tan (or yellow) spot in wheat, which appears to have arisen as recently as 1941 as a consequence of interspecific virulence gene transfer from *Septoria nodorum* (Friesen *et al.*, 2006). Similarly, a novel variant of *Magnaporthe oryzae*, the causal agent of rice blast, has been reported attacking wheat in South America. The origin of this pathogen is unclear as yet but provides a further example of the constantly changing nature of pathogens and their propensity to generate new taxa with the potential to cause significant economic impact.

Sexual recombination events also play a role in the origin of a number of emerging and threatening diseases. Recently, this has been documented in the appearance of a number of *Phytophthora* hybrids. For example, in Europe, hybridization between *Phytophthora cambivora* (an introduced pathogen of hardwood trees) and *P. fragariae* (a pathogen of strawberries and raspberries) has given rise to a group of heteroploid hybrid taxa causing significant destruction to *Alnus* spp. – a host that neither fungal parent is capable of attacking (Brasier *et al.*, 2004). An alternative explanation for the origin of *Phytophthora* spp. *alni* is that it may have been generated on several occasions by hybridization between ssp. *multiformis* and ssp. *uniformis* or their respective ancestor (Ioos *et al.*, 2006).

The Identity of Future Emerging Diseases – Prediction?

As can be seen, there are many examples of diseases that through new ecological opportunities have jumped hosts or

through genetic changes such as recombination have evolved to give rise to major disease epidemics. Understanding the epidemiology and evolutionary biology underlying such processes is a crucial step in understanding the phenomenon of emerging infectious diseases. A major driving force in the epidemiology of any disease association is the interaction of host and pathogen life history features and the way these play out in terms of effective transmission, survival, and reproduction (McDonald and Linde, 2002; Santini *et al.*, 2013). Although each disease has unique features, there are also suites of attributes that permit grouping of different host and pathogen types. Thus, highly host-specific pathogens and those with a broad host range sit at opposite ends of one particular continuum that determines the amount of host material vulnerable to infection in any situation. Highly specific pathogens with clear boom-and-bust epidemiological patterns may be less of a threat than pathogens with broader host ranges. But how stable are these patterns under different environmental conditions? As host range broadens and pathogens become less specific, their impact on any individual host may rise as the total pathogen population size will be determined by the sum of its fecundity on all its hosts – not just on the host of particular focus. In particular polycyclic pathogens with sexual recombination that are able to respond rapidly to benign environmental conditions (climatic or nutritional) are likely to play an important role as increased pathogen populations will increase the likelihood for evolutionary change resulting in new host jumps. However, whether this will be the case or not is likely to vary broadly even among closely related taxa.

Over the past half century, particularly dramatic changes have been observed in Europe among the powdery mildews – including range expansions, new host jumps, and increased disease severity of earlier accidentally infected hosts. For example, four mildews have shown rapid range expansions from the east, one in the 1940s (*Erysiphe hypophylla* on *Quercus robur* and *Q. petraea*), two in the 1980s (*Microsphaera palcewskii* on *Caragana arborescens* and *Microsphaera vanbruntiana* var. *sambuci-racemosae* on *Sambucus racemosa*), and one in the 1990s (*Erysiphe syringae-japonicae* on *Syringia* spp.). At the same time, a further two mildews have moved in from the west, one in the 1950s (*Erysiphe azaleae* on *Rhododendron* spp.) and one in the 1990s (*Erysiphe flexuosa* on *Aesculus* spp.). Understanding the basis for such changes in the biology of individual interactions is vital to attempts to predict future emerging diseases. Furthermore, whether these and similar cases will have long-lasting effects on their respective hosts or whether such epidemics are transient remains to be seen. As demonstrated in the Park Grass Experiment at Rothamsted for the *Blumeria graminis-Anthoxanthum odoratum* system, environments favorable to the pathogen may favor selection for resistance within the host population, thus resulting in low disease levels. However, in situations involving invasive species, rapid evolutionary change like this is dependent on the preexistence of variation for resistance in the host population.

Countering Invasive Plant Diseases

One of the most frustrating aspects of any assessment of invasion ecology and its practical application to disease incursion and control strategies, is the lack of information as to the frequency with which nascent invasion events occur, the proportion of those that fail to gain a foothold, and even the number that do but remain unrecognized due to the low incidence of invading organisms and a general lack of observers on the ground. If this situation applies to visually obvious organisms like potentially weedy vascular plants, it is substantially worse in considerations of plant disease. Even for diseases of agricultural crops where the majority of pathology attention is focused and transfer of untreated material is more or less strictly controlled through quarantine approaches, major disease still spread both naturally and through accidental human-mediated transfer (e.g., *Puccinia striiformis* into Australia and *Tilletia indica* in the USA). Increasingly, a major focus of concern is with the booming global live plant export–import nursery trade where the probability of new emerging disease episodes involving soilborne pathogens is greatly enhanced by insufficiently rigorous controls (Brasier, 2008).

What approaches can be taken to minimize the arrival of diseases into new environments? The standard preinvasion response is one of maintaining effective quarantine barriers (usually at national boundaries). Such an approach provides a generalized response and has some benefits. However, given the mobility of the world's population and the effective dispersal mechanisms of many fungi, this approach, although valuable, is essentially only a temporary one that postpones rather than prevents incursion. Where concern is focused on the possible incursion of specific threatening pathogens, matching of the climatic envelope of pathogen distribution in its native range with that potentially available in the target area has been advocated. For example, this approach has been used to estimate geographic areas of highest risk following the arrival of *Puccinia psidii* in Australia. However, the overall predictive value of climatic matching approaches is often not overwhelmingly compelling and need to take into account a broader range of factors influencing the interaction (e.g., host range, variation in susceptibility and how this might be geographically structured, host community structure, etc.) and the possibility of uncertainty as to the actual taxon involved (Eolith *et al.*, 2013).

With postinvasion strategies, there is a gulf between the options available for the control of diseases of agriculture and those of native ecosystems. Thus, the appearance of a threatening crop disease would typically precipitate a three-phase response. The first stage, that of 'contain and destroy,' is applied when the pathogen is detected at a very early phase, where the area of ingress is limited and (preferably) isolated (e.g., *Phakopsora vinifera* in northern Australia) and/or the pathogen has limited dispersal capability. During this stage, the aim is to eradicate or, failing that, restrict distribution of the pathogen through effective area control. The second stage, 'manage and reduce,' relies on both short-term options provided by agronomic approaches (tillage, rotation cropping, rouging, pesticides) and long-term resistance breeding to ensure that the economic impact of the pathogen is limited in most, if not all, years. Finally, the third phase of 'abandonment' occurs where epidemics cannot be controlled and production is subeconomic, leading to crop replacement. Unfortunately, few of these postinvasion strategies have

application to plant diseases of native ecosystems. In these situations, if a pathogen successfully circumvents border quarantine barriers and initiates infection, the probability of disease detection early enough to affect eradication is extremely small. The management responses available to agricultural enterprises are not relevant and with the exception of the protection of amenity plantings and sites of especial significance, there is little that can be done (cf. the impact of *Cryphonectria parasitica* on American chestnut or the introduction of *Phytophthora cinnamomi* into complex *Banksia*-dominated shrublands in Western Australia).

Conclusions

For a long period, the main focus on new emerging diseases has been related to invasive pathogens that have passed oceanic borders. Nowadays the focus on emerging diseases is increasingly related to global change issues. Although ongoing and future environmental change is more likely to have an impact and may accelerate the emergence of new diseases, it is important to remember that hybridization events and host jumps have regularly occurred during evolutionary time, resulting in the fascinating diversification which now can be seen and understood. Thus, a major ongoing challenge as how to prevent the unwanted impacts of pathogens in agriculture, horticulture, and forestry is foreseen, but in general little, if anything, can be done to hinder them in natural situations.

Glossary

Emerging disease New infections resulting from the evolution or change of an existing pathogen or parasite resulting in a change of host range, vector, pathogenicity or strain; or the occurrence of a previously unrecognized infection or disease.
Endemic Prevalent in or peculiar to a particular locality, region, or people.
Evolution Evolution is the process by which genetic mutations that enhance reproduction become and remain more common in successive generations of a population.
Livestock Livestock are domesticated animals raised in an agricultural setting to produce commodities such as food, fiber, and labor.
Mutation A change in the DNA sequence.
Pandemic An epidemic occurring worldwide, or over a very wide area, crossing international boundaries and usually affecting a large number of people.
Reassortment Mixing of the genetic material of a species into new combinations in different individuals.
Recrudescent Breaking out again: renewing disease after abatement, suppression, or cessation.
Risk factor/determinant A variable associated with an increased risk of disease or infection.
Synergism Interaction of discrete agencies conditions such that the total effect is greater than the sum of the individual effects.
Zoonoses Diseases that is transmissible between vertebrates and humans.

Introduction

Southeast Asia (SEA) is known for its physical, political, cultural, and socioeconomical heterogeneity and is geographically divided into mainland and maritime (or Malay Archipelago) SEA comprising of Cambodia, Laos, Myanmar, Thailand, Vietnam, Peninsular Malaysia and East Malaysia, Brunei, Indonesia, the Philippines, Singapore, and East Timor, respectively. In the past two decades several zoonotic diseases, i.e., diseases that are transmissible between humans and animals (vertebrates), have surfaced in SEA, severely affecting the regional economy and devastating animal and human lives. The disease events reserved SEA as among the regions to be monitored for future emerging zoonotic diseases (Gilbert, 2012).

According to the World Organisation for Animals Health (OIE), emerging zoonoses are "new infections resulting from the evolution or change of an existing pathogen or parasite resulting in a change of host range, vector, pathogenicity or strain; or the occurrence of a previously unrecognised infection or disease" (WHO, 2011). While reemerging zoonoses are existing or endemic (possibly hypoendemic) communicable diseases resurging in terms of their frequency (incidence or outbreaks) or distribution over space and time, emerging zoonotic diseases may arise sporadically due to unique combinations or 'synergism' of several disease drivers, such as those that were seen in the explosive outbreaks of Nipah virus infection, SARS (severe acute respiratory syndrome), and the recent influenza H1N1 pandemic of 2009 (Morens and Fauci, 2013). These events usually attract more attention among the public and scientific community as they can be distinctive in terms of presentation and extraordinary in terms of magnitude, coverage, and socioeconomic implications.

Livestock farming is the principal source of livelihood for most countries in SEA except Singapore and Brunei. SEA is home to an estimated more than 2.65 billion chickens, 245 million ducks, 13.7 million head of buffalo, 46.1 million head of cattle, 71 million head of pigs, 13.8 million head of sheep, and 28.2 million head of goats (FAO, 2014). Animal agriculture and related activities in this region provides employment and side income, improves household dietary components and nutritional security, and provides food and economic well-being for their respective nations' (Randolph *et al.*, 2007). In the past decade, some of the livestock sectors in this region such as the poultry sector have significantly expanded. However, the rate of expansion is not even across the region whereby larger scale poultry farming is propagating, i.e., it is rapid in Thailand and Malaysia, but at a much lesser extent in Vietnam, Indonesia, and Cambodia. Nonetheless, livestock rearing in SEA has remained the practice of smallholders where the majority of livestock are reared in an extensive or backyard system (Ahuja, 2013; Del Rosario *et al.*, 2007). This type of animal husbandry has been linked to several emerging diseases and has been identified as a risk factor for future emerging infections (Biswas *et al.*, 2009; Grace *et al.*, 2012).

The poor 'bear a disproportionately high share of the burden of (zoonotic) disease' because of their close contact with livestock in unsanitary conditions and the low likelihood of needed healthcare (Grace *et al.*, 2012; WHO *et al.*, 2006). This is especially true for farmers in Asia and Africa where human and livestock habitat coalesced in small crowded spaces. Livestock agriculture employs more than 50% of households in SEA, among which more than 60% are maintained as backyard farms where biosecurity is almost impossible to implement. The unsophisticated nature of backyard system allows continuous interaction between various species or animals and humans and has been frequently reported as one of the most important emerging disease determinant in this region. In 2012, International Livestock Research Institute, Kenya produced a comprehensive report about transmission of disease in emerging

 doi:10.1016/B978-0-444-52512-3.00216-3

livestock systems in the developing world, and in the report the institute mapped poverty to zoonoses occurrence worldwide (Grace *et al.*, 2012). SEA was highlighted as among the areas with high concentration of poor livestock keepers where intervention at the human–livestock interface could give positive impacts on zoonoses control. This article will highlight only the major emerging zoonosis and lingering or endemic zoonosis caused by infectious microorganisms originating from domesticated farm animals that have been reported in the SEA region for the last two decades. Non-zoonotic and transboundary emerging animal diseases of food security and economic importance will not be discussed.

Factors Influencing the Emergence of Zoonotic Infectious Diseases among Livestock in Southeast Asia

A combination of factors has been linked to the emergence and resurfacing of zoonotic and non-zoonotic trans-boundary diseases, which have been discussed extensively elsewhere. Briefly, the factors include microbial evolutionary adaptation such as genetic mutation and viral genetic recombination or reassortment, improvement of microbial switching capacities between host species, change in the size of susceptible or reservoir host populations, changes in human behaviors (particularly dietary choices, movement, and travel) and changes in livestock production and animal husbandry practices including animal trade policy, and ecological/environmental alterations such as for agriculture and urbanization (Brown, 2004; Coker *et al.*, 2011). These microbial, host, and environmental factors interact continuously, therefore actions or activities (intentional, natural, or accidental) that modify any of these key elements might generate opportunities for infectious agents to evolve into new ecological niches, access, and eventually adapt in new host systems.

The SEA region is an emerging market arena because of its changing physical and socioeconomic structures and rapidly expanding populations (Delgado *et al.*, 1999; Pingali, 2007). According to FAO (2012), the total population growth of SEA nations will increase from 523 831 in 2000 to 705 414 by 2030 (FAO, 2013; Jones, 2013). The changing population size and growth estimates have energized the livestock industry to meet the doubling protein demands by 2030 and lend impetus to the 'livestock revolution' in the region (Delgado *et al.*, 1999; Steinfeld, 2004). The growing demand for livestock has encouraged movement of animals and increased the exchange of products, services, and materials between countries. This, in turn, offers new opportunities for smallholder livestock producers in the region to market their products. Unfortunately, regional disharmony in disease control measures, surveillance, and implementation also conveniently allow veterinary pathogens to cross regional borders via legal and illegal animal movement and trade (Coker *et al.*, 2011; Liverani *et al.*, 2013).

SEA boasts a large proportion of the global rainforest and biomes. However, in the past century, an overall 1–2% annual decline of the existing rainforest has been recorded due to various reasons including urbanization, severe weather, logging, intensive agriculture, and industrialized animal production. Intensified farming of major commodity crops such as rubber and palm oil have resulted in clearance of large areas of jungle and forest in Indonesia, Thailand, and Malaysia (Miettinen *et al.*, 2011). The increasing consumer demand for animal product motivate local producers to diversify livestock production system innovatively within these plantations, therefore integrated farming system was widely introduced as it economizes on resources and improves farmer's yield and profits (Devendra, 2011; Devendra *et al.*, 1997). The combinations of crop and animal farming have largely and significantly benefitted the local, national, and regional economy. Nevertheless, the current practice of this farming system in SEA may increase risk of emerging infection via ecosystem–livestock–wildlife interface. According to recent literature reviews, more than 60% from approximately 1400 known pathogens to humans originate from animals, out of which more than 77% are promiscuous and readily infect multiple species including humans (Cleaveland *et al.*, 2001; Kuiken *et al.*, 2005; Woolhouse and Gowtage-Sequeria, 2005). The livestock–crop production within the vicinity of forest situates for livestock–wildlife pathogen exchange. These pathogens may become sustained among wild animals, complicating the control and eradication of livestock diseases. Domesticated animals at the ecosystem–wildlife interface provide a continuous supply of susceptible hosts for the amplification, evolution, and adaptation of novel pathogens from wildlife, serving as important passage for the pathogen to move from wildlife to humans (Chomel *et al.*, 2007; Liverani *et al.*, 2013). Human-origin or anthropogenic disturbances of wildlife ecosystem have in the past led to the emergence of previously unencountered disease agents or organisms blamed for catastrophic disease events such as those seen in the outbreaks of Nipah and SARS (Hughes *et al.*, 2007; Jones *et al.*, 2013).

Impact of Emerging Zoonoses on Southeast Asia

Impact on Food Security

Emerging zoonoses affect food security in two ways; gross reduction at the level of animal production and reduction in numbers of available food animals due to disease or compulsory culling to control the spread of infection to humans. For example, between 2003 and 2013, highly pathogenic avian influenza (HPAI) H5N1 in SEA resulted in the culling of a total of 175 million domestic birds (Van Kerkhove, 2009). In many countries, backyard and small poultry producers were the worst affected. Small- and medium-scale commercial poultry producers had to sell their properties and close their farms when chickens died or were culled whereas backyard producers lost their main source of protein and income (Rushton *et al.*, 2005). At the height of the outbreaks between 2003 and 2005, the production of broilers dropped significantly throughout the region. Thailand, for example, was the fourth largest poultry meat exporter in 2003 exporting nearly 485 000 tonnes of poultry meat. Immediately following the avian flu notification by the Thai authorities in 2004, poultry products were banned from major international trade flows which significantly drove the exportation of poultry down by 50% from 2003, destabilizing the local and regional markets broiler meat supply (Otte, 2008). In Malaysia, reported

clustered outbreaks of H5N1 among a flock of smuggled fighting cocks drove Singapore to restrict chickens and eggs imported from Malaysia as a precautionary measure to the perceived risk. As a result of the sudden reduction of supply of these produce, the price of chicken and eggs increased markedly in the local market (Agri-Food and Veterinary Authority of Singapore, 2004; Nicita, 2008), lowering consumer's purchasing power for basic necessities. Fortunately, the outbreak was rapidly controlled by the veterinary authorities and customer confidence and trade was therefore restored.

The worldwide outbreak of pandemic influenza A H1N1 2009 was initially linked to pigs because the genetic makeup of the virus partly includes swine-originated influenza genes (Malik Peiris *et al.*, 2009). It was apparent in the course of the outbreak that pigs played no active role in the pandemia and the epidemiology of the disease, but because of the partial genetic affiliation, the media-friendly 'swine flu' was used in reference to the disease (WHO, 2009). The term led to serious misunderstanding among consumers about the safety of consuming pork and pork products worldwide. As a consequence, many refrained from purchasing pork, leading to domestic and regional pork markets downturn. In fact, pork-importing countries within the region considered introducing trade restriction on live pigs as precautionary measures to safeguard the local pig industries and preserve human health (Johnson, 2009). At the same time, various groups in the region further insisted on stamping out all pigs to reduce risk of disease, even when neither viral evidence nor infection was observed. Outside of SEA, in Egypt, mass pig slaughtering was performed amidst fear of virus spread (Gusman, 2009). However, prompt risk communication emphasizing the lack of danger posed by pigs or pork restored consumer confidence and minimized the potentially disastrous consequences to the pig production industry in the region.

Impact on Human Health

The overall disease burden to human health is usually expressed as disability-adjusted life year (DALY), which measures the year lost due to ill health, disability, and early death (Lopez *et al.*, 2006). However, the true burden of emerging and reemerging zoonoses is difficult to estimate due to the lack of comprehensive information and systematically collected data worldwide. The OIE reported zoonosis to cause at least 2.4 billion cases of illness and 2.2 million deaths every year (Grace *et al.*, 2012). Reemerging zoonoses, which are often considered neglected, are the hardest to estimate because the prevailing cases occur in underdeveloped or developing nations including SEA, where data are not available or poorly recorded, stored, and managed. Systematic reports of cases – if present – are often not accessible and questionable data integrity makes estimation of disease impact challenging. However, it is universally accepted that zoonosis among livestock have in the past and will continue to cause extensive human sufferings and deaths. Classical zoonosis such as brucellosis, for example, resulted in major disability and debility of military personnel during World War II with more than 1300 cases reported in the US Army between 1942 and 1945 (Wyatt, 2013). Many soldiers contracted brucellosis through consumption of contaminated raw milk and cheese and later had to be discharged because of severe debility as a result of prolonged fever and complications caused by arthritis. The disease has continued to contribute to the global burden of human illnesses and sufferings (Dean *et al.*, 2012; Pappas *et al.*, 2006) especially in developing nations such as Syria and Mongolia. Recent emerging zoonoses such as HPAI H5N1 killed 383 of 647 infected people worldwide since 2003 while avian influenza H7N9 has resulted in 145 infections with 45 deaths (WHO, 2013) since early 2013. Novel Nipah virus infection in Malaysia and Bangladesh caused more than 270 deaths and chronic debilitating post-encephalitic conditions to many others.

Impact on Social and Economy

A recent study estimated the costs of major highly fatal zoonoses between 1997 and 2009 to be US$80 billion (World Bank, 2012). The socioeconomic impact of zoonoses includes the loss incurred from reduced livestock production, trade restrictions, declined consumers demand for products, and disease control/prevention activities including surveillance efforts. In addition, it includes the indirect cost of depressed economic activities of other businesses dependent on the livestock industry such as animal feed manufacturers, animal-related food producers, food retailers, and hospitality services (Otte *et al.*, 2004; Rushton, 2009). Non-affiliated activities such as tourism can also be negatively affected as reported during the outbreak of SARS and pandemic influenza H1N1 2009 (Coker *et al.*, 2011; Lau *et al.*, 2009).

The socioeconomic repercussion of emerging zoonoses was well documented for Nipah disease event in Malaysia (Ng *et al.*, 2009). The outbreak resulted not only in the culling of over one million pigs but also bankrupting town economy when residents moved away from affected areas. Nipah essentially destroyed the local pig industry at the time and the livelihood of many pig farming families. For example, an estimated 36 000 employment opportunities in the farms and other local business that were supported by the farming activities diminished and local town and real estate businesses had to close down when pig farm operations liquidated. The value of destroyed pigs was estimated at US$97 million with additional US$35 million losses for compensation paid by the government and US$120 million in trade to Singapore and Hong Kong (Nor and Ong, 2000). The effect of Nipah rippled or spread to other pig affiliated industry causing indirect losses to pig feed industry, oil and fats, utility, and real estate which amounts to RM 541 million (US$164 million) (Hosono *et al.*, 2006). Following the outbreak, the number of pig farms dropped from 1800 prior to January 1999 to only 796 after 21 July 1999 (Nordin, 2001) with most pig farmers leaving the pig industry for other livestock or unrelated animal farming opportunities.

On a larger scale, the HPAI H5N1 epidemic in the region had a similar impact as the Nipah outbreak in Malaysia. Direct losses to the poultry sector were as the result of massive culling of affected and at-risk flocks with estimated cumulative losses of up to US$10 billion between 2003 and 2005 in SEA alone (FAO, 2005). However, more costs from the disease ensued indirectly. For example, Malaysian exporters reported a combined loss of RM 2 million per day (US$526 000) as a

result of the trade restriction to Singapore, a 20% drop in local consumer demand for chicken, and a consequential reduction in the average chicken price. Additional costs were incurred from concurrent control measured implemented such as movement controls, active and passive surveillance, and public awareness campaigns. Malaysia spent an estimated US$50 000 per month in 2005 on movement control alone (FAO Regional Office for Asia and the Pacific, 2006). During the outbreak, Vietnam and Indonesia had to embark on mass vaccination of poultry as the number of human cases increased and had to invest in cold chain assurance of the vaccine, training of vaccinators, and mass communication campaigns. The total costs of delivering vaccinations alone during the first year of vaccine implementation in these countries were estimated to be US$22 million (Pongcharoensuk *et al.*, 2011).

Emerging Viral Zoonoses in Southeast Asia

Nipah Virus Infection

Between late 1997 and early 1998 a mysterious 'barking pig syndrome' appeared in a pig farm at a northern state of Peninsular Malaysia that rapidly spreads to the central states (Mohd Nor *et al.*, 2000). The disease in pigs was closely linked to clustered cases of febrile encephalitis among individuals occupationally exposed to pigs and led to the discovery of the novel Nipah virus (Chua *et al.*, 2000). In the initial phase of the outbreak, the clinical signs observed in pigs ranged from mild to severe respiratory symptoms with variable neurological signs, but with prevailing low mortality rates. A distinctive dry hacking cough from infected pigs resulted in the coined 'barking' syndrome which could be heard from a distance away. Within an incubation period of 7–14 days of exposure to infected pigs, farmers, and abattoir workers showed neurological clinical symptoms related to meningitis such as hypotonia, areflexia, segmental myoclonus, disorientation and confusion, and convulsion, which rapidly progressed to coma and death (Chua, 2003; Lam and Chua, 2002). The case–fatality rate from those infected was 40%, where 106 deaths occurred among the 265 infected by the end of the outbreak in 1999. Individuals who survived the infection had prolonged or permanent disabilities and approximately 8% of those who survived succumbed to recurrent neurological disease due to viral recrudescence (Chong and Tan, 2003; Tan *et al.*, 2002).

The Nipah virus, named after the location where the disease was first discovered at Sungai Nipah, Negeri Sembilan is antigenically and genomically similar to the Hendra virus isolated from bats in Australia and was later classified into a distinct taxonomic unit as the new genus *Henipavirus* of the family *Paramyxoviridae* (Chua *et al.*, 2000). A retrospective analysis of serum stored at the Veterinary Research Institute in Ipoh, Perak later indicated that the agent may have been circulating in the pig population in Malaysia as early as the mid-1990s. However, the impact among pigs may have been insignificant and humans were not affected allowing the disease to go unnoticed. Pigs were identified as the amplifier host for Nipah virus, resulting in the culling of approximately 1.1 million pigs as part of the outbreak response (Mohd Nor *et al.*, 2000; Nor and Ong, 2000). Most, if not all pig farming in Malaysia is done intensively, therefore culling was performed swiftly and efficiently via local intersectoral and interagency efforts. Backyard pig farming being uncommon in Malaysia combined with the fact that pig farms were located at a certain distance away from the residential areas may have helped curb the magnitude and spread of the outbreak. The culling of pigs was followed closely by diminishing cases of the disease among humans. Nipah outbreak has not been reported since.

Pteropus bats (flying foxes or fruit bats), which were found at the index farm, have since been proven in many studies to be the symptomless reservoir host of the virus (Halpin *et al.*, 2011; Rahman *et al.*, 2010; Yob *et al.*, 2001). The species that have been well studied for Nipah virus infection are *Pteropus vampyrus* (large flying fox) and *Pteropus hypomelanus* (island flying fox) (Chua *et al.*, 2002b; Epstein *et al.*, 2009; Rahman *et al.*, 2010, 2011, 2013; Yob *et al.*, 2001). Pteropid bats have coevolved with the virus over time and are more likely to shed the virus during reproductive seasons or following stressful events (Halpin *et al.*, 2011; Rahman *et al.*, 2011, 2013). Infected bats shed the virus in secretions and excretions such as saliva, urine, semen, and feces (Halpin *et al.*, 2011). Apart from bats in Malaysia, serological evidence of Nipah virus has been found in pteropids trapped throughout SEA such as Cambodia, Indonesia, and Thailand (Reynes *et al.*, 2005; Sendow *et al.*, 2006; Wacharapluesadee *et al.*, 2005), a finding that is not surprising given the distance traveled and migratory nature of these bats (Breed *et al.*, 2010; Epstein *et al.*, 2009). The spill-over event may have occurred when bats which were believed to have migrated from Borneo were attracted to fruit trees planted around pig farms and near pig pens, a practice that was abandoned following the Nipah. Pigs may have consumed partially eaten fruits contaminated with fluids or excreta from the bats. The virus was then amplified in pigs and consequently spilled to in-contact farm workers resulting in the outbreak (Chua *et al.*, 2000; Mohd Nor *et al.*, 2000). Outbreaks have not occurred in other countries that reported serological evidence of Nipah antibodies among sampled bats and no evidence of seroconversion have been reported in humans or domesticated animals in the respective countries.

The emergence of Nipah in Malaysia is unique and has since been linked to the extraordinary convergence of climatological and ecological drivers which created an ideal situation for the virus to surface (Chua *et al.*, 2002a; Epstein *et al.*, 2006; Field *et al.*, 2001). Complex interaction between urbanization, deforestation, and extreme climate changes were believed to have driven the bats from their natural ecosystem to another in search of food. At present, Malaysia has remained free from the Nipah disease and pigs screened in the yearly Nipah serosurveillance have not shown any evidence of Nipah virus antibodies. Nipah outbreaks have continued to occur in Bangladesh, where an obvious amplifier host has not been identified and the human-to-human transmission that was unobserved in the Nipah outbreak in Malaysia was evident (Homaira *et al.*, 2010; Hsu *et al.*, 2004).

Emerging Influenza A Viruses

Influenza viruses are members of the family *Orthomyxoviridae*, a group of single-stranded, negative-sense ribonucleic acid

(RNA) viruses and are classified on the basis of antigenic differences among their nucleopcapsid and matrix proteins as Influenza A, B, and C. Of these three, only influenza A viruses are established in different animal species including humans, horses, swine, and a wide variety of domesticated and wild birds. Influenza A viruses are further divided into subtypes based on the antigenic relationships of their hemagglutinin and neuraminidase surface glycoproteins (Lee and Saif, 2009). These viruses inhibit the gut of wild waterfowl, its natural reservoir, but are highly capable of evolving in aberrant hosts. Influenza A have been successful in developing various mechanisms to jump species – into domestic poultry, farm animals, and humans after undergoing 'genetic shift,' a periodic gene segment reassortment between host species that produce significant antigenic change improving virus capabilities to infect new host species (Chen *et al.*, 2004; Webster *et al.*, 1992).

Highly Pathogenic Avian Influenza A H5N1

The HPAI H5N1 causes severe morbidity and mortality among poultry and was the first avian flu to cause severe respiratory disease and high mortality among humans. In SEA, the reported case-fatality rate of H5N1 infection in humans vary between 50% and 80%, however the rate is acknowledged to be inflated due to an undetermined number of individuals who may have been silently or subclinically infected during the outbreaks (Le *et al.*, 2013; Wang *et al.*, 2012). The incubation period of H5N1 in chickens is tricky to measure but has been estimated to be between 2 and 3 days (Bouma *et al.*, 2009; Jeong *et al.*, 2009) in experimental settings after which highly variable clinical presentation developed that includes respiratory symptoms such as ocular and nasal discharges; coughing; snicking; dyspnea; swelling, of the sinuses and/or head; severe depression; reduced vocalization; marked reduction in feed and water intake; and cyanosis of unfeathered skin, wattles, and comb. Incoordination and nervous signs, diarrhea, drastic decline in egg production, and increased poor-quality eggs and sudden deaths (high mortality of up to 100%) were also reported. In domestic ducks, with an exception of rare sporadic outbreaks most HPAI viruses produce few clinical signs (Chen *et al.*, 2006; Ellis *et al.*, 2004). Viral transmission may occur when infected birds shed the virus via discharges from its body (saliva, respiratory discharges, and feces), or via contaminated fomites (feed, water, etc.) to susceptible hosts. Once exposed to infectious birds, the incubation period for susceptible humans have been reported to range between 3 and 9 days (Huai, 2008) leading to initial symptoms of headache, myalgia, diarrhea, sore throat, and rhinorrhea followed by fever, cough, and shortness of breath. At a later stage of infection, severe lower-respiratory-tract symptoms and deaths were frequently reported. The case-fatalities for H5N1 infection in humans varies between countries within the region depending on several factors such as accessibility to medical care, culture and belief of people, and the socioeconomic standing of the country's general population.

H5N1 virus has emerged as early as 1996 in farmed geese in Guangdong Province of southern China but was not notable until the H5N1 virus made a dead-end jump from poultry to humans in Hong Kong in 1997, where the outbreaks of H5N1 infection in poultry coincided with severe respiratory infection and fatalities in humans (Chan, 2002; Guo *et al.*, 1998). Avian influenza was formally reported in SEA in Vietnam at the end of 2003. The infection rapidly spread in the country's poultry population where severe respiratory infection and lethality occurred among poultry and humans. Within a few ensuing months the disease had spread to Thailand, Cambodia, Indonesia, Laos, and Malaysia (Sims *et al.*, 2005; WHO, 2012). Most outbreaks occurred among backyard poultry with instances of virus transmission to local commercial poultry farms usually via fomites (such as trucks, crates, and cages) and personnel. Even though the poultry industry is the major livestock industry undergoing rapid intensification in this region, 50–70% of poultry are raised in backyard farms where little biosecurity exists (Bethe, 2006; Boni *et al.*, 2013).

The risk factor for infection of H5N1 in human has been well reported. A paper published by Van Kerkhove provides a comprehensive review on the modes of virus transmission (Van Kerkhove, 2009). Consistent with the widely practiced backyard farming system, the most important and consistent risk factor for human infection across studies involves varying level of contact or exposure to live infected poultry. Direct contact when handling sick birds, consuming uncooked poultry products, and caring for sick poultry are some of the significant determinants found in most human avian influenza outbreaks. The environmental risk factor include local animal trade pattern (such as informal trading in the local community and trading live animal in markets), extent of surveillance and early detection, density of live animal markets, poultry husbandry system, density of free ranging chicken and ducks, and rice cropping intensity. Live poultry market is one of the most discussed determinant for avian flu (and a few other emerging zoonoses). This type of market supplies 'warm' meat preferred by most Southeast Asian countries and is widely found in this region. However, the activities and environment of the market apparently promote virus from infected birds to circulate and spread to other birds and humans via aerosolized virus particles, blood, or body fluids (Fournié *et al.*, 2012; Van Kerkhove, 2009). A few countries in SEA have since discouraged operations of live poultry markets to reduce the risk of emerging diseases. However, little success has been achieved in this effort because of cultural affiliations of this practice to the people in this region. Changes can only be seen with public education and awareness, and implementation of regulations by the local authorities.

Since its emergence in 2003 to January 2014, the World Health Organization has tallied 650 human confirmed cases of avian influenza and 386 deaths worldwide (WHO, 2014). SEA contributed to more than 50% of the cases and fatalities related to human H5N1 infection. Based on the formal notification to OIE between 2003 and 2013, Vietnam surpassed other nations in the world with 2682 outbreaks followed by Thailand with 1141 outbreaks. Indonesia, Myanmar, Cambodia, Laos, and Malaysia each reported 269, 114, 37, 19, and 16 outbreaks, respectively. Malaysia and Thailand have not reported any outbreaks since 2006 and 2009 respectively. HPAI H5N1 outbreaks were better controlled in a few SEA regions compared to others. The success in eradicating H5N1

Table 1 The human cases and deaths due to highly pathogenic avian influenza H5N1 from 2003 to 2013

Country	*2003–09*		*2010*		*2011*		*2012*		*2013*		*Total*	
	Cases	*Deaths*	*Cases*	*Deaths*	*Cases*	*Deaths*	*Cases*	*Deaths*	*Cases*	*Deaths*	*Cases*	*Deaths*
Cambodia	9	7	1	1	8	8	3	3	17	10	38	29

virus depends primarily on early detection of virus introduction and prompt institution of control measures such as aggressive culling or stamping-out policy in the country (Coker *et al.*, 2011; Eagles *et al.*, 2009; OIE and FAO, 2007).

Indonesia and Vietnam were the worst countries affected by H5N1 in terms of human incidence and fatalities, which by the end of 2004 and 2005, respectively instigated the decision to perform mass vaccination of poultry (OIE and FAO, 2007). The vaccination was performed along with other control measures such as systematic annual testing and pre-movement testing of local poultry. Both countries have since been considered endemic for avian influenza H5N1. By 2006 Indonesia reported H5N1 outbreaks in 31 of its 33 provinces and 286 of 444 its districts (Sumiarto and Arifin, 2008). Even as this article was being written, Vietnam, Indonesia, Cambodia, Laos, Myanmar, and Indonesia continue to face intermittent outbreaks despite significant control efforts by the governing authorities. However, the incidence and the number of outbreaks in poultry along with those in humans has continuously declined over the past few years consistent with the declining global trend of avian influenza H5N1 worldwide (**Table 1**).

Pandemic Influenza A (H1N1) 2009 Virus

Between March and early April 2009, a novel influenza A (H1N1) virus emerged in the United States among individuals with travel history to Mexico (Novel Swine-Origin Influenza A (H1N1) Virus Investigation Team *et al.*, 2009; Malik Peiris *et al.*, 2009). Initial cases of influenza were later discovered to have occurred in Mexico before it was reported in the United States (Neumann *et al.*, 2009). The virus rapidly spread to the whole northern hemisphere and within the first few months had spread throughout the globe via human-to-human transmission leading to the first global influenza pandemic of the century. The virus was discovered to be the result of novel assortments of triple reassortant avian/human/swine (that include genes from classical swine influenza H1N1, North America avian H1N1, and human H3N2) and Eurasian avian-like swine viruses (Neumann *et al.*, 2009). Phylogenetic analyses suggest that both triple reassorted and Eurasian avian-like swine viruses have become established in the swine population in the late 1990s before the discovery of the novel H1N1. However throughout the outbreak period, no evidence of novel H1N1 infection occurred in pigs other than the possible human to pigs virus transmission on a pig farm in Canada (Howden *et al.*, 2009). It was concluded that even though components of the virus originated from pigs in the past, pigs did not play immediate nor active role in the transmission and epidemiology of the virus in the 2009 pandemia (Johnson, 2009).

The pandemic H1N1 struck almost every SEA countries, and post-pandemic surveillance among pigs in Thailand, Cambodia, and Vietnam suggest that reverse transmission of pandemic H1N1 2009 virus infection had occurred at rates of more than 20% among sampled pigs (Hiromoto *et al.*, 2012; Rith *et al.*, 2013; Sreta *et al.*, 2010; Trevennec *et al.*, 2012). Several phylogenetic analysis work indicated that human-to-swine pandemic H1N1 influenza virus transmission event is not uncommon, a finding that has also been observed for other human seasonal flu viruses (non-pandemic H1 and H3 influenza viruses) therefore implicating human as a significant contributor to the genetic diversity of influenza viruses in swine (Lycett *et al.*, 2012; Nelson *et al.*, 2011). Several episodes of reverse transmission of the virus from infected humans to pigs later proved that pigs will demonstrate very mild flu like symptoms on infection before recovery and can sustain the virus within the flock (Howden *et al.*, 2009; Pereda *et al.*, 2010; Rith *et al.*, 2013; Song *et al.*, 2010; Sreta *et al.*, 2010). At present, there was little evidence to suggest that the virus can be transmitted from infected pigs back to human. However, the finding indicated that countries must improve biosecurity measures at the human–swine interface as pigs are highly efficient in viral recombination and reassortment and thus may impact the human health somewhere in the future.

Low Pathogenic Avian Influenza H7N9

At the beginning of 2013, another avian influenza virus strain of low pathogenicity, H7N9 resulted in severe respiratory infection among humans. The infection first appeared in the southern part of China and later spread to a wider region within the country (CDC, 2013; Gao *et al.*, 2013). The infection in humans are severe and resulted in high case–fatality, however there was little clinical implications to poultry even though epidemiological evidence among human cases highly suggest some level of contact (direct or indirect) with this species (Chen *et al.*, 2013; Lee *et al.*, 2013). Fortunately, the low pathogenic avian influenza (LPAI) H7N9 have to date not been reported among the poultry populations of the SEA countries or any other countries. Many SEA countries imposed

temporary restriction of poultry importation from China to safeguard its substantial poultry farming industry and preserve human health (Lim, 2013; Tuổi Trẻ News, 2014).

Reemerging Endemic Bacterial Zoonoses

Bovine Tuberculosis

Bovine tuberculosis is a classical zoonotic debilitating disease mainly caused by Gram-positive acid-fast bacilli *Mycobacterium bovis* and to a lesser extent *Mycobacterium caprae*. These two species are members of the *Mycobacterium tuberculosis* complex group within the genus *Mycobacterium*. Other species included in this group are *M. tuberculosis*, *Mycobacterium africanum*, *Mycobacterium microti*, *Mycobacterium canettii*, *Mycobacterium pinnipedii*, and *Mycobacterium mungi* (Acha and Szyfres, 2001). Bovine tuberculosis may occur not only in cattle but a wide species of domesticated and wild animals. Bovine species (both domesticated and wild) other than cattle such as buffaloes and bison, and Cervidae such as deer and elk are especially susceptible; however, all warm-blooded species can be infected. Transmission of pathogen between animals occurs via aerosols, ingestion of the organism from contaminated materials, or inoculation via open wound. The incubation period for the disease is highly variable ranging from months to years. The animal may remain asymptomatic for a long period of time following infection, with some proportion of animals remaining latently infected lifelong. Granulomatous lesions or tubercle formations either generalized or localized is a major characteristic of tuberculosis. Infected animals will shed *M. bovis* in respiratory secretions, feces, and milk, and sometimes in the urine, vaginal secretions, or semen. The most usual form of tuberculosis is manifested via a low-grade fluctuating fever, weakness, inappetence, and chronic weight loss leading to progressive emaciation; however, acute and fulminating infection has also been reported (Cosivi *et al.*, 1998). Coughing is not pronounced in animals until lesions occur in the lungs. The chronic development of disease manifestations accompanied by lack of high or immediate mortality often masks the importance of tuberculosis; therefore it is widely believed that prevalence of bovine tuberculosis is under-reported worldwide.

Bovine tuberculosis also referred as 'zoonotic tuberculosis' is a disease of animal production and public health importance. It causes significant economic losses in countries with large cattle farming industry through loss of production, markets and trade, and additional expenditures from surveillance and control programs (Amanfu, 2006; Butler, 2010). SEA with estimated cattle and buffalo populations of more than 110 million (FAO, 2014) will be threatened if the disease is not well controlled. Even though data on bovine tuberculosis prevalence is not available in this region, it can be speculated that the production loss from the disease among cattle will be consistent to what has been observed in developed countries where data are systematically gathered. Accordingly, milk production of infected cattle was reported to decline up to 10% and infected cows had one fewer calves (Cosivi *et al.*, 1998). In countries where food safety regulations are implemented, meat inspection at the abattoir detect clinical signs of tuberculosis such as progressive emaciation and tubercle lesions in the organs, prompting immediate carcass condemnations (Biffa *et al.*, 2010). The impacts of bovine tuberculosis on public health increased where disease is highly endemic and especially affect populations with weakened immune system such those living with HIV/AIDS (human immunodeficiency virus infection/acquired immunodeficiency syndrome) (Cosivi *et al.*, 1998). Conservative estimates reported SEA having more than 3.5 million with HIV (SEARO, 2014), therefore at higher risk for infection compared to the general populations.

For centuries, zoonotic tuberculosis has contributed to the incidence of tuberculosis among humans worldwide. Similar to pathogen transmission between animals, zoonotic transmission of *M. bovis* from animals to human occurs primarily through consumption of contaminated animal products, most commonly unpasteurized milk but may also occur through other mentioned modes (Acha and Szyfres, 2001). However, incidence of zoonotic tuberculosis markedly declined following the introduction of pasteurization and structured veterinary disease control programs (Cousins, 2001). In general, zoonotic tuberculosis is reported to be responsible for approximately 3–15% of tuberculosis among humans worldwide (Michel *et al.*, 2010; Müller *et al.*, 2013). The rate varies with regions of the world depending on several factors such as veterinary disease control program and food safety regulation in the country. Cosivi *et al.* (1998) estimated zoonotic tuberculosis to be responsible for at least 15 000 DALYs per year (27 DALYs per 100 000 population) in SEA based on the conservative estimate of worldwide proportion of tuberculosis caused by *M. bovis* at 3.1% (Cosivi *et al.*, 1998). Estimation of *M. bovis* contribution to human tuberculosis in SEA is difficult because most laboratories in the region have insufficient capacity to isolate and culture the organism and differentiate *M. bovis* from *M. tuberculosis*, the predominant causal agent for human tuberculosis.

As with many other neglected or lingering infection in developed countries, information about bovine tuberculosis in countries within SEA is scarce or difficult to find. Many disease review efforts suggested little or no data from SEA countries can be accessed via mainstream scientific publications by which burden of the disease can be extrapolated. Evidence obtained from literatures for this article, although few, suggest that tuberculosis is increasingly observed among livestock (and reservoir) in this region, however the prevalence is highly variable. For example, evidence of bovine tuberculosis were found among buffaloes in Thailand at a high rate (Chanepaiboon *et al.*, 2000) and spatial analysis among dairy herds conducted in Thailand suggests herd-level prevalence of 10% and within herd prevalence of between 10% and 30% (Inchaisri *et al.*, 2003). However, limited study on bovine tuberculosis in the neighboring Laos suggested low prevalence at 1% (Vongxay *et al.*, 2012). No other data can be obtained from other parts of SEA even though efforts of controlling bovine tuberculosis are being actively conducted by many SEA countries veterinary services through test-and-slaughter policy combined with abattoir surveillance (FAO, 2012). Formal reports for diseases such as bovine tuberculosis are difficult to obtain due to multiple reasons including poor resource gathering and analytical supports, and lack of priority or emphasis

by respective countries' service institutions for publication of printed materials.

There are several important risks factors for the emergence of tuberculosis among cattle in SEA. The consistent determinants as reported for most underdeveloped or developing nations are lack of structured disease control programs at the farm level and inadequate disease surveillance by local veterinary authorities (Michel *et al.*, 2010; Müller *et al.*, 2013). Testing and culling system is highly resource intensive, therefore might not be performed adequately in many SEA resource-poor areas. Extensive livestock husbandry practices predominantly integrated or mixed farming practices provide additional challenges to disease control because animals may not be easily accessed for disease testing and monitoring. In addition, integrated farms in SEA are mostly located in the peri-urban areas where livestock dwellings coalescence or encroaches wildlife habitats, thereby improving disease spread at the livestock–wildlife and vice versa interface (Daszak *et al.*, 2012; Jones *et al.*, 2013). Wild animals are important reservoirs for *M. bovis* and many sophisticated disease-control strategies in developed nations failed to eradicate *M. bovis* because the organism perpetuates in sylvatic cycle (De Lisle *et al.*, 2001; Gortazar *et al.*, 2011; Nugent, 2011; Schmitt *et al.*, 2002). Wildlife reservoirs may continue to infect susceptible cattle despite avid testing and culling strategies of infected herds. SEA has abundant wildlife and endangered species that can be severely affected if bovine tuberculosis is not controlled. Evidence of tuberculosis infection in wild animals are been seen in a few SEA countries such as Malaysia and Thailand (Angkawanish *et al.*, 2010; Ong *et al.*, 2013). Moreover, wild boars and cervids that frequently roamed in integrated farm areas are well described as maintenance host of *M. bovis* for other domestic and wild animals in many parts of Europe and New Zealand (Jackson, 2002; Meng *et al.*, 2009; Vicente *et al.*, 2006). Tuberculosis among wildlife provides a unique challenge because sylvatic tuberculosis cannot be eradicated through animal testing and culling of precious or protected wildlife species. Any disease interventions will involve complex decisions from various sectors and authorities including the veterinary, wildlife and conservation authorities; biologists; wildlife and ecologists; environmentalists; and the general public (De Lisle *et al.*, 2001).

The WHO (World Health Organization) has recently declared a state of emergency for tuberculosis worldwide. Cambodia, Indonesia, Thailand, and Vietnam reported among the highest incidence of tuberculosis in the region between 2009 and 2013 (WHO, 2013). Tuberculosis in humans is predominantly caused by *M. tuberculosis* which can reversely be transmitted to cattle and a number of other animal species through close contact with infected farm workers or individuals (Ameni *et al.*, 2013; Krajewska *et al.*, 2012; Ocepek *et al.*, 2005). However, the significance of animals as reservoir for *M. tuberculosis* and perpetuator of the infection has not been well documented. Emerging markets in this region demand large human capital investment and services. Therefore, workers from countries ranked with high burden of tuberculosis must be screened before starting work in livestock farms as they can potentially transmit the infection to animals.

Brucellosis

Brucellosis, a disease with many names (Malta fever, undulant fever, Gibraltar fever, etc.) is another classical zoonoses that has lingered for decades and is showing signs of reemergence among animals and humans in this region. Brucellosis is listed as among the most widespread zoonosis worldwide but is often neglected in developing countries. The disease is caused by Gram-negative acid-fast stained bacilli of the genus *Brucella*. Several species of *Brucella* affect animals, however the most important disease-causing species for livestocks are *Brucella abortus*, *Brucella melitensis*, and *Brucella suis*, responsible for bovine, caprine or ovine, and pig brucellosis respectively. Species of *Brucella* are mainly host-restricted however *B. melitensis* has the capacity to infect across the mammalian species and is especially known for its virulence as compared to other species (Acha *et al.*, 2001; Pappas *et al.*, 2006; Seleem *et al.*, 2010).

Brucellosis causes major livestock production losses and is a significant threat to public health. In female animals, brucellosis typically causes abortion at the last stage of gestation. In farms where animal breeding is structured, for example, through synchronous breeding methods, multiple abortions or 'abortion storm' occur acutely in a herd or flock when the organism was first introduced. Infected animals shed *Brucella* via milk and may have subsequent normal parturitions where the organism will be shed through uterine discharges (Renukaradhya *et al.*, 2002). Shedding of the organisms may be lifelong with high proportion of infected animals becoming chronic *Brucella* carriers. In countries of SEA where majority of herd sizes are small and backyard or extensive system predominates, explosive abortions is not typical but seropositive farms will report higher rates of abortion and stillbirths. Lower milk yields of up to 25% have been recorded among infected herds (Acha *et al.*, 2001). In males, organisms are shed via semen and brucellosis may cause orchitis and infertility. The mortality rate is very low ($<2\%$) but extensive morbidity is common within a herd. Brucellosis among humans appear to be directly correlated with the prevalence of brucellosis among livestock as humans contract the infection mainly via consumption of unpasteurized milk or milk products, but may also be infected from eating infected meat, or direct contact with aborted materials from diseased animals. Human to human transmission is rare, therefore control of incidence in humans is best achieved via systematic control of brucellosis among animals. Once exposed to the organism, the incubation period for brucellosis in susceptible animals and humans is variable but ranged from 2 to 4 weeks. The initial sign for human brucellosis includes nonspecific flu-like symptoms of undifferentiated prolonged (undulant) fever, myalgia, and arthralgia with generalized inflammation of the reproductive organs. Clinical manifestations among males include orchitis and epididymitis.

Recent overview of global brucellosis burden indicated absence of data and studies on human brucellosis in SEA (Dean *et al.*, 2012). On the contrary, published data on brucellosis in animals are available but limitations include accessibility and language. Sufficient scientific and local publications exist to indicate that infection is endemic among livestock and is widely spread within respective countries.

Sporadic reports of cases and outbreaks in humans occurred in Thailand, Malaysia, and Indonesia due to various degrees of exposure to infected animals and animal products (Bamaiyi *et al.*, 2011; Danusantoso *et al.*, 1972; Jama'ayah *et al.*, 2011; Paitoonpong *et al.*, 2006; Wongphruksasoong *et al.*, 2012). The reemergence of brucellosis was reported in Thailand in 2003 where *B. melitensis*, a species that has not been reported in Thailand, was first isolated (Manosuthi *et al.*, 2004). Serological surveillance for *B. abortus* in Thailand estimated the prevalence rate of 3.3% in dairy cows (Jittapalapong *et al.*, 2008) with high herd level of 24.1%. In 2009, a large human brucellosis outbreak which caused three deaths was linked to goat herding in a local Thai village (Wongphruksasoong *et al.*, 2012). In certain provinces the seroprevalence among beef cattle reached up to 40% and among sheep and goats, the prevalence ranged from 10% to 20%. In Vietnam, reports of brucellosis in livestock are absent, nonetheless a study on the undifferentiated fever among patients in Vietnam reported 15.8% *Brucella* serologically positive patients (Nga *et al.*, 2006) suggesting that *Brucella* is indeed present among animal populations of Vietnam. In Indonesia, the seroprevalence of *B. abortus* differs widely, ranging between 0% and 46% with high prevalence rate in most provinces of Pulau Jawa and Nusa Tenggara (Putra, 2006). In South Sulawesi, the seroprevalence of brucellosis among Bali beef cattle is high at 19.3% (Mu¯ihanah *et al.*, 2013). In other parts of Indonesia, the cattle- and herd-level seroprevalence has been reported to be as high as 15–44.5% (Lake *et al.*, 2010), respectively, while the seroprevalence among pigs was 12.6% (van der Giessen and Priadi, 1988). In Malaysia, brucellosis among cattle and goats has lingered for many decades at a low prevalence rate but incidence progressively surged in the early 2000–10 following massive importation of live cattle and goats from *Brucella*-endemic countries late in 1990s. In 2010, several clustered outbreaks of *B. melitensis* among humans were linked to the increasingly popular practice of consuming raw goat's milk (The Star, 2010). Nationwide serosurveilance data suggest that serological evidence for bovine brucellosis of less than 3% is low at animal level but relatively high (21.7%) at herd or flock level (Anka *et al.*, 2013). The direct loss due to brucellosis to the farmers and government estimated from *B. abortus* infection from production losses, carcass condemnation, culling, compensation, and vaccination was approximately RM38 million (US$11 million) for 2010 (Anka, 2014). *Brucella melitensis* have a lower seroprevalence of 0.9% and 7% at caprine level and flock level in Malaysia (Bamaiyi *et al.*, 2010). In the Philippines, porcine brucellosis was a problem in the late 1950s; however, new information is not available to ascertain the current status (San Agustin and Castillo, 1950).

The risk factor of brucellosis in SEA among livestock has not been well studied. However limited studies published in Malaysia and Indonesia suggest that epidemiology of the disease in this region is similar to those in other developing countries (Al-Majali *et al.*, 2009; Muma *et al.*, 2007). Studies on herd-level risk factors for seroreaction to *Brucella* among cattle in Malaysia and Indonesia show extensive farming system to elevate the risk for bovine brucellosis (Anka *et al.*, 2013; Lake *et al.*, 2010). The frequency of wildlife encounter in this farm system is common and therefore was speculated to significantly contribute to the prevalence. As with bovine tuberculosis, wildlife are important reservoir and maintenance host of *Brucella* organism allowing for reintroduction of new infection into clean herds at the wildlife–livestock interface (Bengis *et al.*, 2004; Godfroid, 2002; Meng *et al.*, 2009).

Disease control and eradication program for brucellosis is carried out by most veterinary authorities in SEA countries at different capacities, implementation level, and range of available resources. In some countries such as Indonesia and Malaysia, eradication activities are accompanied by vaccination programs of infected herds to maintain low level of brucellosis at farm level. However, the implementation of vaccination program is mostly irregular, therefore benefits from the vaccination for brucellosis may be hard to assess. In countries where culling accompanied by compensation scheme is carried out, the amount of compensation disbursed generally need improvement as farmers often wavered from culling seroreactors when their losses are not adequately compensated.

Leptospirosis

SEA is endemic for leptospirosis as evident from the continuous reports of human leptospirosis cases and outbreaks. In the last decade, many countries within this region are seeing an increasing number of leptospirosis among humans and the disease has become one of the most important reemerging zoonosis (Pappas *et al.*, 2008; Victoriano *et al.*, 2009). Leptospirosis causes wide range of nonspecific symptoms that may be confused with flu, malaria, dengue hemorrhagic fever, hepatitis, scrub typhus, and many other febrile infections and may be accompanied by acute renal injury or acute lung injury, with case fatalities of 12–25% (Hartskeerl *et al.*, 2011; WHO, 2010). Thus, in countries where these diseases are endemic, leptospirosis is often underdiagnosed, and therefore underestimated. Thailand, Vietnam, Indonesia, and Malaysia have listed leptospirosis as one of the notifiable infectious disease in humans and a disease of priority to control at the respective country's national level.

Leptospirosis is caused the pathogenic spirochete from the genus *Leptospira* which consists of 17 species and more than 250 serovars that are categorized as pathogenic, intermediate, and nonpathogenic leptospirae. The taxonomy of leptopira is highly complex and can be confusing. The article by Bharti *et al.* (2003) provides excellent review on the classification of leptopira and will not be repeated here. Several species are reported more than others in causing clinical infection in both animals and humans which includes *Leptospira interrogans, Leptospira alexanderi, Leptospira fainei, Leptospira inadai, Leptospira kirscheri, Leptospira meyeri, Leptospira borgpetersenii, Leptospira weilii, Leptospira noguchii*, and *Leptospira santarosai*. *Leptospira* serovars may be clustered within geographical region and within a given region only 10–20 serovars are typically found. A number of serovars are found unique and clustered within limited region, however most serovars can be found across geographical boundaries (Nalam *et al.*, 2010). Most mammalian species including domesticated livestock and wildlife are reservoirs of pathogenic leptospires. Some serovars of leptospirae appear to prefer a single host species, however

little information exist about host preference of leptospirae to warrant claims of host specificity (Bharti *et al.*, 2003). Rodents, particularly, have probably coevolved with the spirochete, therefore are highly efficient as the reservoir. The high mobility of rodents further increased their effectiveness as reservoir host and perpetuator of the agent. Other mammals may also serve as important source of the leptospira. Infected mammal may excrete the leptospirae intermittently for months or lifetime thereby increasing the risk for those occupationally exposed to animals such as farmers, slaughterhouse workers, pet traders, veterinarians, rodent catchers, and sewer workers (McBride *et al.*, 2005; Vinetz, 2001).

In SEA, agricultural workers such as paddy or rice farmers are at higher risk of infection compared to individuals of other occupations (Padre *et al.*, 1988; Rafizah *et al.*, 2013; Seng *et al.*, 2007; Tangkanakul *et al.*, 2000, 2005); however, most clinical cases in humans are as a result of environmental contaminations following climatological events such as flooding (Amilasan *et al.*, 2012; Ivanova *et al.*, 2012; Kawaguchi *et al.*, 2008; Lau *et al.*, 2010) or recreational activities (Mortimer, 2005; Sapian *et al.*, 2012; Sejvar *et al.*, 2003). For agricultural workers, the risk is possibly associated with frequent contact with water bodies where livestock are used to assist in plowing the fields and pests such as rats comingle and secrete leptospires. The exact animal species secreting the pathogenic Leptospirae is often difficult to determine as pathogenic serovars often occur in multiple species. SEA has a favorable weather for the survival of leptospira as pathogenic leptospires prefer warm and humid climate (Levett, 2001; Victoriano *et al.*, 2009).

Most literatures from the region suggest that livestock is potentially an important reservoir for pathogenic leptospirae however prevailing evidence indicated that livestock may not be an important source of human infection in the SEA region (Chanepaiboon *et al.*, 2000; Kawaguchi *et al.*, 2008; Van *et al.*, 1998; Victoriano *et al.*, 2009). Clinical leptospirosis in cattle or pigs is rarely reported in any of the SEA countries therefore their clinical, production, public health, and economic implication are unclear. Much of the publications on livestock and leptospirosis in SEA focused on serological surveillance and serovar identification, not their actual role in clinical or human infection. According to literatures, within 10–14 days following exposure, clinical signs of cattle and swine leptospirosis include fever, abortion, still birth, infertility, and milk reduction (Arundel and Radostits, 2000). However, little information could be found on the clinical leptospirosis in livestock in this region, therefore the associated economic or production impact due to leptospirosis is unclear. A study in Vietnam suggest that infection with some leptospira serovars may reduce one live pig born per litter, equivalent to 8% loss of production (Boqvist *et al.*, 2002), no other studies can be found in Asia. In Laos, the serological surveillance using microscopic agglutination test (MAT) suggested that in cattle the leptospirosis prevalence is 53.6% and in pigs 22.7%, however the clinical impact of the prevalence was not evident. Moreover rice field farmers in Laos have significantly higher exposure to the organism whereby 88.7% were leptospira seropositive as compared to 9.3% in livestock farmer (Kawaguchi *et al.*, 2008; Vongxay *et al.*, 2012). In Malaysia, the work on livestock was performed in mid-1980s by Bahaman *et al.* who reported seroprevalence of leptospira species among domestic livestock in Malaysia to average of more than 20%, with highest seroprevalence observed among cattle (40.5%), buffaloes (31%), and pigs (16%) (Bahaman and Ibrahim, 1988, 1986; Bahaman *et al.*, 1987). However, cases of leptospirosis among livestock have never been reported leading many to suggest that leptospirosis is not an important disease of livestock in Malaysia. Furthermore, incidence of leptospirosis in humans in Malaysia is usually associated with recreational and urban exposures rather than agricultural farming activities. Similar observations were recorded in many countries within SEA. Study in Thailand noted little difference in the prevalence of leptopspira antibodies of various livestock between areas where leptospirosis was highly endemic and not endemic among humans. The prevalence of antibodies found using MAT in epidemic provinces was 77.2% in cattle, 86.1% in buffalo, and 60.4% in swine and similar prevalence was observed in nonepidemic province (69.8% in cattle, 82.2% in buffalo, and 62.5% in swine) (Suwancharoen *et al.*, 2000). In general, available evidence at present suggest that livestock is largely exposed to leptospirae organism but manifested little observable clinical signs. Therefore leptospirae may not be a significant agent for disease and production losses among livestock in this region. Livestock might be as important reservoir of leptospira, however their role in the epidemiology of leptospirosis in humans in this region is vague and need to be enlightened with additional studies.

Conclusion

SEA is an arena of emerging markets with human population that is expected to double by 2030. Livestock industries need to significantly expand to ensure adequate protein supply for the growing and more affluent human populations. To increase animal production, various measures were undertaken including expanding agricultural areas and increasing diversity of livestock production systems. Unfortunately these acts are often not supported by increasing environmental and public health regulations in this region. Increased animal movement across borders through legal and illegal trade will continue to occur as long as there is surplus demand for animal proteins. Without harmonization of regional disease controls and strengthening of veterinary disease control programs, emerging disease especially those that had been neglected will continue to threaten regional livestock industry. Deforestation and fragmentation of ecological niches in an effort to expand agriculture land have significantly benefited the local and regional economy and improved society's wealth. However, without doubt these activities are associated with emerging and reemerging infection of production animals in this region. Many infectious diseases in humans originated from animals and agricultural expansion and intensification/diversification promotes disease emergence through ecosystem–livestock–human interface. In addition, encroachments of livestock into wild animal habitat enhance disease transmission at livestock–wildlife interface. The spread of these infections would threaten regional food security and safety. Emerging zoonoses causes major losses through reduced economic activity directly from trade restriction that is often prompted by a nation's

precautionary behavior. The ripple effect from reduction in economic activity can spread to other livestock-related sectors at the national and international levels. Emerging and reemerging infection causes additional cost to the country through general precautionary and preventive measures such as establishment of quarantine station and procedures, restriction of animal importation, premovement testing, vaccination, surveillance, and monitoring. Tremendous downturn in livestock-affiliated economic activity and shock to livelihoods of those affected by the disease warrant collaborative interministrial and intersectoral efforts at national and international level to minimize emerging diseases in livestock and humans.

Energy and Greenhouse Gases Footprint of Food Processing

RO Morawicki and T Hager, Fayetteville, AR, USA

© 2014 Elsevier Inc. All rights reserved.

Introduction

The levels of energy consumption and emissions during food processing are difficult to generalize. Even when the food industry uses some common processes, for example, drying, centrifugation, refrigeration, freezing, etc., most food products have specific processes to transform the raw materials into processed foods. Energy consumption and emissions depend not only on the type of product, but also on the degree of processing, the processing technique, and the form of energy used. Low processed foods, for example, some fruits, vegetables, and tubers, require minimal energy at the processing stage, which normally consists of cleaning, sorting, and packaging. For other products that require cooking right before eating, energy consumption is generally transferred from the processing to the consumer step. At the highest end of the energy consumption spectrum during processing are the ready-to-eat products. This is not because of the energy consumed to process the food, but also because most ready-to-eat products are commercialized chilled or frozen.

Processing techniques that involve phase changes – drying, evaporation, distillation, and freezing – are energy intensive when compared to other processes. The type of energy used also plays an important role. The food industry uses two types of energy: thermal and electric. With the exception of some industrial parks with district heating, most of the thermal energy in food processing plants is generated by burning fossil fuels, which may also be used to generate electricity; however, some industries are able to burn byproducts of the processed food to reduce the consumption of fossil fuels. Depending on the technology and the age of the equipment, the efficiency of transforming chemical energy contained in the fuel into heat is generally 80% and above.

Electricity is mostly purchased from utility companies. Electricity is a high quality energy source because it is versatile and can be transformed easily into mechanical or thermal energy with high efficiencies. Unfortunately, the global efficiency of electricity from fuel to the processing plant gate is low because of the efficiency loss when transforming chemical energy into mechanical energy at the generation facilities. Efficiencies are normally 30% or less for regular coal or natural gas fired plants, or approximately 40% for combined cycles. Transmission of electricity also has losses that depend of the distance and the type of transmission lines. Owing to the conversion efficiencies and losses, electric and thermal energies cannot be added directly when calculating the total impact of energy consumption during processing. Therefore, there are two ways of reporting these energies. One is by reporting thermal and electric energy values individually, and the second is by expressing as the value as primary energy, which is a back calculation to the chemical energy contained in the fuels.

A consequence of energy use is the emission of carbon dioxide (CO_2), methane (CH_4), and nitrogen oxides (NOx). However, emissions also arise from intended or unintended escape of hydrofluorocarbons (HFCs) from refrigeration equipment, and CO_2 from processes, particularly the fermentation industry and wastewater treatment.

When analyzing energy consumption of food processing plants, two approaches can be followed: by process and by industry; and this article follows the 'by industry' approach. Owing to the involvedness that would require covering all food processing industries, a selected number of industries have been chosen for this article. The greenhouse gases (GHGs) section focuses on the generation of electricity and thermal energy, which are the main sources of emissions, and the emissions from refrigeration equipment.

Industries

Beer

Beer is a fermented beverage made from malted cereal, hops, yeast, and water; and carbonated in most cases. Malted cereals are the result of soaking the cereals in water, allowing them to germinate, and stopping the germination by drying right before they become a plant. The purpose of malting is to develop enzymes that in subsequent steps breakdown the starch into fermentable sugars. Barley is the grain of excellence for beer making because of the high concentration of enzymes generated during the malting process, but it is rarely used alone. Barley is generally combined with other malted and unmalted grains like rice, wheat, oats, rye, and, in some cases, corn and sorghum. Malted and unmalted grains are milled and mixed with enough water to form a paste, called the 'mash,' which is subjected to a progression of specific temperatures to allow enzymes to break down high molecular weight carbohydrates. Soluble compounds are then extracted from the mash by trickling water in a process called lautering that yields a dark sugary liquid, wort. The wort is filtered and subsequently concentrated by boiling, which also serves to reduce the microbial load. Also, hops are added during boiling. Once cooled the resulting liquid is fermented with either *Saccharomyces cerevisiae* to produce ale beers or *Saccharomyces uvarum* for lagers. *S. cerevisiae* is a fast-acting yeast that rises to the top during fermentation that is conducted at temperatures between 15 and 25 °C and can be completed in around a week. *S. uvarum*, however, is a slow fermenter that sinks to the bottom during fermentation and requires temperatures between 4 and 13 °C, which extends the fermentation process and requires a maturation step that can take a month or longer (Beer-FAQ, 2007). After fermentation, subsequent steps include conditioning, filtering, carbonation, and bottling.

Lagers are the most popular beers in the world. Large-scale breweries produce exclusively lagers, whereas ales are preferably crafted by smaller breweries and microbreweries. As a result of the popularity of lagers, there are more data on energy consumption available, because most life cycle assessments in

Table 2 Energy consumption at different stages of beer making

Process	*Thermal (MJ l^{-1})*	*Electricity (MJ l^{-1})*	*Total (MJ l^{-1})*	*Source*
Cooling		0.144		Talve (2001)
Fermentation including clarification			0.121	Cordella *et al.* (2008)
Maturation		0.054[1]		Talve (2001)
Malting			0.857	Cordella *et al.* (2008)
Wort production			0.952	Cordella *et al.* (2008)
Mash infusion	0.37		0.029	European Commission (2006)

the literature have been conducted for lagers, especially in Europe. Therefore, data presented in this section will correspond exclusively to lager-type beers produced in different regions of Europe. Data on energy consumption for the production of beer are limited. Table 1 presents the total energy consumed to produce 1 l of lager at different breweries. Some sources express energy consumption as total energy in a broad range varying from 0.61 to 3.4 MJ l^{-1} without indicating if this is primary energy. Other sources separate energy into thermal and electric with relatively high variation in the reported values. When analyzing by processes (Table 2), malting and wort production are the most energy intensive operations. This is not unexpected because malting requires drying and wort production relies heavily on boiling, which are both highly tasking in terms of energy use.

Bread

Industrial bread production consists of three major processes: (1) mixing and fermentation; (2) proofing; and (3) baking (Figure 1) (Giannou *et al.*, 2003). There are three standard industrial mixing and fermentation techniques for typical breads – conventional straight dough, Chorleywood, and sponge and dough (Martin, 2004; European Commission, 2006). The straight dough process consists of step-wise mixing then fermentation. The sponge and dough is similar to the conventional process, but fermentation is conducted before the conventional mixing (during the sponge phase) using an optimized ingredient ratio (Martin, 2004; Mondal and Datta, 2008). The remaining flour is mixed in after the sponge phase during the conventional dough mixing phase. The Chorleywood is an alternative that utilizes rapid mechanical shear with chemical modifiers to facilitate dough development to reduce the processing length (Martin, 2004). The Chorleywood method is more common in European countries, whereas the sponge and dough method is typically used in the US (Martin, 2004), but smaller and artisanal bakeries may use the more traditional approach. Particularly with the emphasis that Europe has placed on energy efficiency and the larger per capita bread consumption – as much as three times greater than in the US (Clyma, 2007) – the faster Chorleywood process is likely preferred to save energy and produce more bread at a faster rate. Unlike typical breads, sourdough bread requires significantly longer proofing time (up to 24 h), because the process relies on the growth of lactic acid bacteria (as well as yeast) (European Commission, 2006).

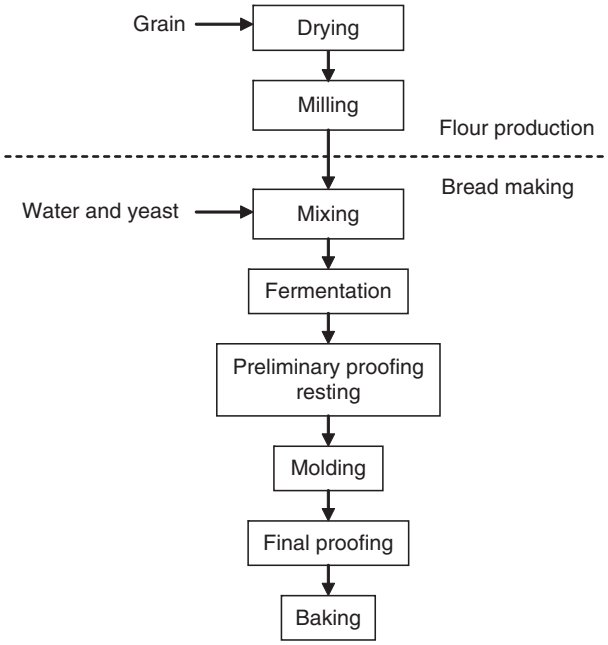

Figure 1 Flow diagram of the basic steps in flour production and bread making.

Table 3 Reported energy requirements for bread processing[a]

Subcategory (i.e., product, facility size, energy source)	*Thermal (MJ kg^{-1})*	*Fuel (MJ kg^{-1})*	*Electricity (MJ kg^{-1})*	*Total energy (MJ kg^{-1})*	*Source*
Large industrial bakery[b]	2.5		1.5		Andersson and Ohlsson (1999)
Small industrial bakery[b]	0.2		1.75

Wheat	1.0		0.07		
Rye	1.0		0.07		
Frozen wheat	1.0		0.79		
Crispy rolls				2.4–6.9	Le-Bail *et al.* (2010)
Large bakery 1 (oil and electric for energy)[e]	3.0		1.01		Thompsson (1999)
Large bakery 2 (only electric)[e]			1.7		
Small bakery 1 (oil and electric for energy)[e]	3.8		1.03		
Small bakery 2 (only electric)[e]			2.23		
NS	3.0–6.16		0.24–0.87		Wojdalski *et al.* (2007)

[a]Some values include grain milling and drying, whereas others do not; thus, some differences may be attributed to the additional requirements associated with these processes.
[b]Estimated from Figure 5 in p. 33 of Andersson and Ohlsson (1999).
[c]Includes overhead energy consumption.
[d]Steam (megajoules per kilogram).
[e]Excludes milling and drying.
Note: NS, not specified.

Following the mixing and fermentation step, the dough is divided, permitted to rest (initial proofing), and molded to the desired shape (**Figure 1**) (Martin, 2004). The dough subsequently enters the proofing chamber (consisting of elevated temperature and humidity) to permit CO_2 production (leavening) within the dough (Mondal and Datta, 2008; Le-Bail *et al.*, 2010). Once the dough has reached the optimum volume, it proceeds to the oven for baking in either a batch or a continuous oven. Baking is a complex process consisting of physico-chemical changes such as dehydration, protein coagulation, starch gelatinization, gas exchanges, and Maillard browning (Vanin *et al.*, 2009). These changes occur in two major phases: (1) heating the dough and (2) the crust formation and browning (EU Freshbake, 2006; Le-Bail *et al.*, 2010).

Owing to the heating requirements for baking, bread production is a relatively energy-intensive process (**Table 3**). Larger industrial bakeries generally utilize fossil fuels and electricity for a variety of logistical reasons, whereas local, small, and medium bakeries rely more heavily on electricity (EU Freshbake, 2006). In facilities utilizing fuels as well as electricity, thermal energy is typically used for baking (EU Freshbake, 2006) and total consumption ranges from 2.4–6.9 MJ kg^{-1} (**Table 3**). In those same facilities, electricity is used for the other processes (including mixing and molding), and the electricity usage ranges from 0.2–1.5 MJ kg^{-1}. For more modern facilities that utilize primarily, or exclusively, electricity, the bread production process requires 1.75–2.2 MJ kg^{-1}. Overall, large-scale production can reduce specific energy consumption for processing; however, it is important to note that overall efficiency of production must take into consideration other factors, that is, greater transport distance from a large production facility to the consumer (Andersson and Ohlsson, 1999).

The actual bread-baking process utilizes less than 19% of the energy required by ovens during baking (Le-Bail *et al.*, 2010). Steam is added to the oven during baking to raise the humidity to enhance the quality of the final product, that is, volume, shape, and appearance. Steam generation requires approximately 16–25% of the energy for baking (Le-Bail *et al.*, 2010; EU Freshbake, 2006). The remaining energy is lost via oven walls or exhaust (29–60%), evaporation (15–35%), and heating of cooking devices/components (9–25%) (Le-Bail *et al.*, 2010). Preheating batch ovens can also be a considerable loss of energy with the specific energy consumption highly dependent on the number of batches that are processed. For example, preheating for one batch may require as much 6 MJ kg^{-1}, but processing 12 batches can reduce the specific energy to approximately 2 MJ kg^{-1}.

Canned Foods

Canned products must be pasteurized or sterilized to be regarded as safe during storage at room temperatures. Typically, before thermal processing, the raw materials are sorted, cleaned, modified (i.e., chopped, peeled, destemmed, homogenized), and combined with other ingredients, including sauces, brines, and additives. Once the cans are filled and sealed, they proceed to retorts or water baths for sterilization or pasteurization. The product is subjected to steam or submerged in water for precise time-temperature combinations to ensure safety and, depending on the product, may be subjected to agitation to facilitate the process.

Canned goods are shelf-stable products that can be divided into low and high acid foods. Low acid (pH > 4.6) canned products have to undergo commercial sterilization to insure a reduction of *Clostridium botulinum* spore counts for at least 12-logarithmic cycles. Because *C. botulinum* spores are not a concern when the product pH is less than 4.6, high acid foods are pasteurized at temperatures at or below 100 °C to eliminate organisms (i.e., molds) that cause microbial deterioration. Thus, low-acid foods require more intense thermal processing than high acid foods. Because heating the center of the product is the primary goal, other factors that impact heat penetration can also affect the extent of processing and energy required. Some of these factors include the size of the product pieces, rotation of the production during processing (i.e., still vs. rotary retort), thermal conductivity of the contents, homogeneity of the product, and size and shape of the can or jar.

Although canning is highly dependent on thermal processing and requires more processing energy than fresh products, it is generally less intensive than other processes – freezing and dehydration – that are also used to reduce microbial deterioration (Buffington and Zar, 1977). Singh (1986) reported that the fossil fuel requirements for thermal processing of fruits and vegetables averages approximately 2.6 MJ kg^{-1} product; the electricity requirement for all other aspects of the process was only 0.19 MJ kg^{-1} (**Table 4**). Other values reported for thermal processing fruits and vegetables range from 1.2 MJ kg^{-1} for tomatoes to 8.4 MJ kg^{-1} for canned peas. According to the European Commission (2006), tomatoes, generally processed as a high acid food following a pretreatment to guarantee proper pH values (Derossi *et al.*, 2011), required 0.75–0.85 kg steam per kilogram of final product.

Coffee

Postharvest processing of coffee berries is biphasic (**Figure 2**). In the first phase, the outer layers of the cherry are removed (milling) and the beans are dried. The second phase of coffee processing involves roasting the green beans to generate the desirable coloring and characteristic flavors associated with coffee drinks. Although the whole, roasted beans are fully processed, other products may also be generated from the roasted beans such as ground coffee and instant coffee products (Humbert *et al.*, 2009). Green beans may also be subjected to decaffeination processes.

Typically the first phase of processing is conducted near the site of harvest. Depending on the variety and the desired product, the coffee cherries undergo a dry or wet process (Gonzalez-Rios *et al.*, 2007; Mussatto *et al.*, 2011). Arabica (*Coffea arabica*) beans are processed via both the wet and dry method, depending on the harvesting region, whereas robusta (*Coffea canephora*) beans are primarily processed by the dry method (ICO, 2013). The dry milling method is the simplest and typically involves solar drying the whole cherry to the desired moisture content (11–12%), although mechanical dryers can also be used to facilitate the process (Viere and Schaltegger, 2007). For the wet method, the exterior layers – skin and pulp – of the cherry are mechanically removed with water and the remnant pulp, mucilage, is removed via fermentation (Mussatto *et al.*, 2011) or machine (Gonzalez-Rios *et al.*, 2007). The beans are subsequently dried to obtain the

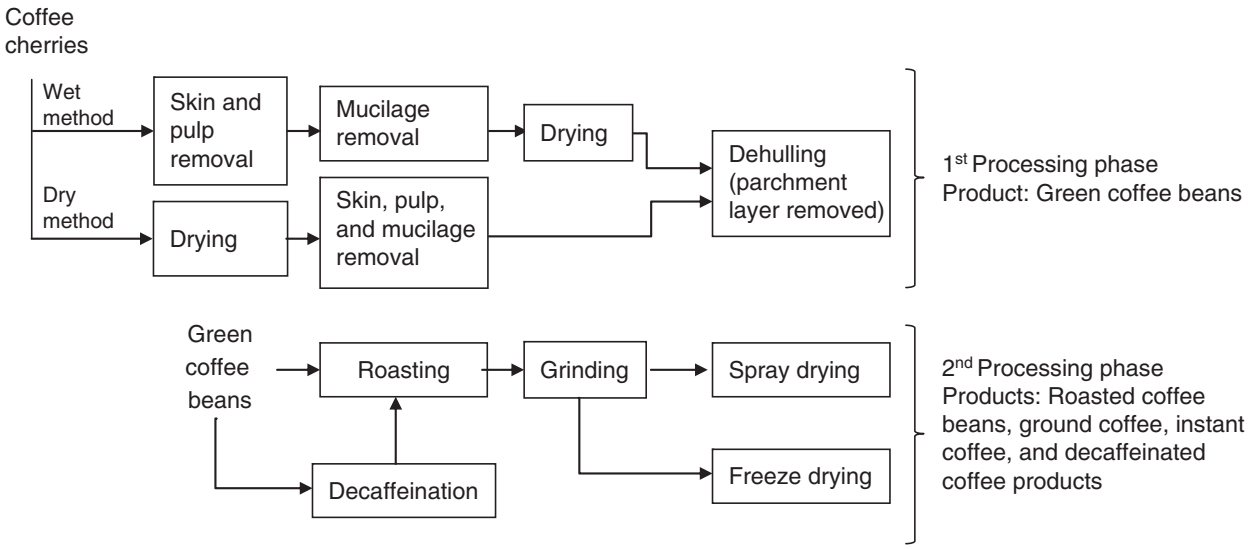

Figure 2 Flow diagram of the two phases of coffee processing.

proper moisture content. This process may involve sun-drying, the use of standard rotary drum dryers, or solar-powered dryers (Trubey, 2004). The final step of wet and dry milling is dehulling to remove the final layer – the parchment – and produce the green bean that is ready for roasting (ICO, 2013).

Owing to the immense variation in the milling and drying phase of coffee processing, the energy requirements differ extensively, particularly because the dry milling process requires significantly less energy than the wet milling process. The greater energy requirements of the wet process can be partially mitigated by the implementation of direct solar drying or solar-powered machinery during wet processing (Trubey, 2004). To complicate matters further, however, the potential to use direct solar drying (for either milling process) is geographically dictated, because climates with predominantly high humidity conditions would limit the radiant heat drying capacity. In addition, some facilities utilize fossil fuels (i.e., LPG), whereas others use firewood for the processing. One study cited a report by the European Commission (originally published in 2003) indicating that milling (unspecified type) required 0.16 MJ electricity per kilogram of green coffee beans and 1.8 MJ fuel per kilogram of green coffee beans (Ramirez *et al.*, 2006). Molina (2009) reported that wet milling electricity requirements ranged from 0.86–1.2 MJ kg^{-1} green coffee beans and firewood inputs ranged from 0.001–0.002 m^3 kg^{-1} of green coffee produced. Standard mechanical drying reportedly requires as much as 0.003 m^3 of firewood and 0.23 MJ of electricity per kilogram of green coffee (Trubey, 2004); thus, a significant portion of the energy requirements in the first phase is attributed to the drying process.

Whole green beans are roasted for 1–15 min between 180 and 240 °C to obtain the desired flavor, aroma, and color qualities (ICO, 2013). Roasted beans can be packaged and sold to consumers as whole beans or ground coffee or can be further processed to make instant coffee. Ramirez *et al.* (2006) reported that the production of roasted coffee required 2.2 MJ of fuel and 0.6 MJ of electricity per kilogram of coffee beans. However, an earlier report indicated that the total energy requirements may be as great as 12.4 MJ kg^{-1} of coffee bean (Pierotti *et al.*, 1977). In a recent LCA of green bean processing, the production of roasted, ground coffee required 2.6 MJ of fossil fuel per kilogram of product and 0.5 MJ of electricity per kilogram of product (Humbert *et al.*, 2009). However, the European Commission (2006) showed that the use of highly efficient roasters and water mist cooling of beans may reduce the processing requirements by 75% with the most efficient roasters using as little as 0.18 MJ kg^{-1} of roasted beans. In fact, according to Solomone (2003), improvements in the energy usage during the roasting phase should be emphasized over other aspects of coffee production.

For instant in coffee production, coffee is 'brewed' in the processing plant and the aqueous fraction is isolated from the spent grounds. Following concentration (by freeze concentration or evaporation), the liquid fraction is either spray-dried or freeze-dried to produce a granulated, soluble form of coffee (Sivetz and Desrosier, 1979). To manufacture spray-dried instant coffee from green beans, the specific energy requirements are very high – 30.2 MJ of fuel per kilogram of coffee and 8.3 MJ of electricity per kilogram of coffee (Humbert *et al.*, 2009). However, innovative methods to recover waste heat could potentially reduce energy demands during extraction (European Commission, 2006).

Corn Milling

Corn is processed according to two different methods: dry and wet. The dry process starts with dry kernels that are milled into a meal and used primarily for the fermentation industry, including ethanol and beverages. In the wet process (**Figure 3**), however, corn is fist soaked in water for 20–36 h at temperatures of 50 °C (Keller and Heckman, 2006) in what is called steeping, which generates a light steepwater byproduct rich in soluble compounds that is then concentrated by evaporation to produce heavy steepwater. Solids contained in the heavy steepwater are separated, mixed with fractions from other parts of the process, dried, and used as animal feed. The liquid

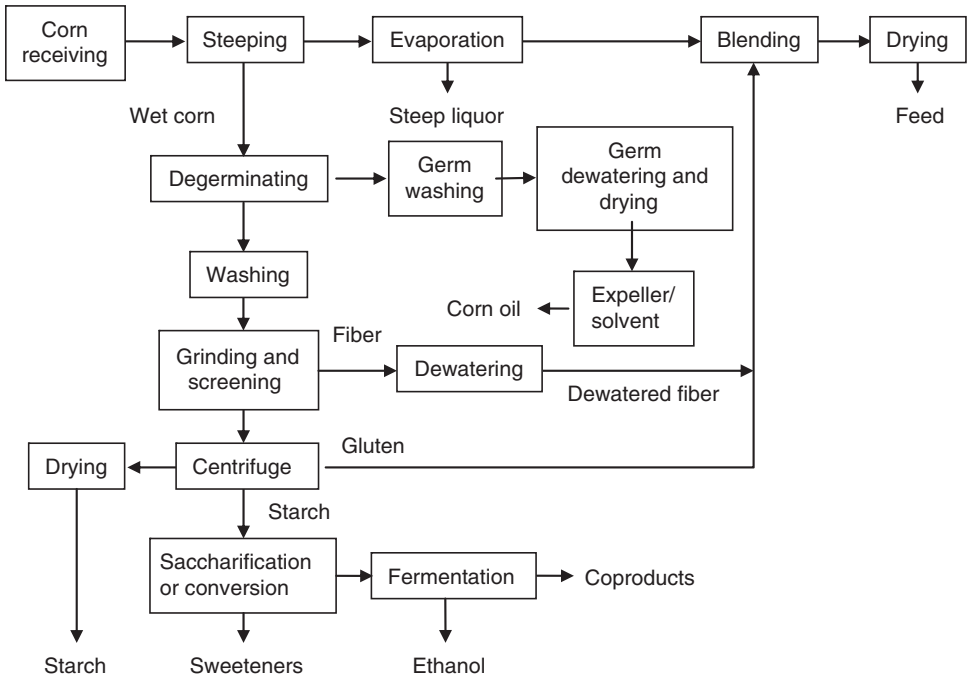

Figure 3 Simplified overview of a wet corn milling operation. Adapted from Keller and Heckman, 2006. Assessment Plan for Corn Steep Liquor (CAS #66071-94-1) in Accordance with the USEPA High Production Volume Chemical Challenge Program. 28 November 2006. Washington, DC: The Corn Refiners Association and EPA (Environmental Protection Agency) US, 1995b. Chapter 9: Food and agricultural industry, Section 9.9.7 corn wet milling. In Emission Factor Documentation for AP-42. Washington, DC: Environmental Protection Agency Office of Air Quality Planning and Standards Emission Inventory Branch.

stream is a concentrate of 40–60% solids called steep liquor, a basic nutrient in ruminant animals feed preparation, fermentation industry, and production of carboxylic acids (Keller and Heckman, 2006).

The corn kernels containing approximately one-third of the water added during steeping are processed in a germ separator, where the germ is removed and after drying used for the extraction of corn oil. The remaining material is washed and ground to produce a stream of hulls and a slurry containing starch, gluten, and other soluble organic compounds (EPA, 1995b). The hulls are combined with concentrated solids from the production of corn steep liquor and spent germs from the extraction of oil to produce, after drying, corn gluten feed. The slurry goes through a centrifuge that separates gluten, which after drying becomes gluten mill, and slurry that goes to a storage tank and from there used to produce modified and unmodified starch, dextrose, fructose, ethanol, etc.

Wet corn milling is an energy intensive operation because it involves dewatering, evaporating, and drying, all processes that requires significant amounts of energy. **Table 5** presents recent data for a wet corn milling operation of a scale of approximately 100 000 bushels a day (1 bushel of corn = 56 pounds = 25.4 kg) in the US. The table presents energy intensity in terms of incoming corn. Because of the assortment of products generated by the process and lack of mass flow data, it is not possible to allocate the specific energy expenses per unit of mass of different products.

In the dry process, dehulled corn kernels are first ground and then cooked, generally using a jet cooker. With the addition of enzymes, starch contained in the cooked slurry is transformed into glucose that then is used primarily to produce ethanol via fermentation. According to Tsiropoulos *et al.* (2013), using unspecified data sources from European facilities, it takes approximately 130 ton of corn to produce 88 ton of starch; and 1 ton of starch produces 1.1 ton of glucose. The energy requirements to convert corn into glucose are between 6.8 and 9.3 MJ kg^{-1} (Tsiropoulos *et al.*, 2013).

Dairy

Raw, unprocessed milk transported to a manufacturing plant can be processed into a plethora of dairy products, but one of the most common is pasteurized, homogenized liquid milk. To generate this commodity, fresh whole milk undergoes several processes – clarification, separation, homogenization, and pasteurization – before packaging (Korsstrom and Lampi, 2001). Clarification is the process of removing large particulates or contaminants from the milk; and separation is the process of separating the fat (or cream) from the skim milk (UNEP, 2000). Then the cream and skim milk are reunited in the proper proportions to generate the desired milk fat content (standardization) and homogenized. If necessary, the product may also be subjected to a flash heat treatment to remove undesirable aroma – deodorization. Finally, the milk is pasteurized to eliminate pathogenic microorganisms and to decrease spoilage microorganisms, thus extending the shelf approximately −4 °C for 10–28 days (Partridge, 2008). Although the requirements for pasteurized liquid milk are fairly low compared to other dairy products (**Table 6**), according to UNEP

Table 5 Estimated energy consumption for different processes in wet corn milling, based on a plant capacity of 100 000 bushel per day

Process	*MJ/(ton of corn)*			
	Electricity	*Steam*	*Fuel*	*Primary energy*
Corn receiving	18			54
Steeping	9	131		158
Steepwater evaporation	22	810		878

[b]Estimated from figure.

[c]Calculated from data in figure without UF membrane.

(2000), the specific energy requirements for pasteurized milk in some dairy processing plants can still be reduced up to 75% on implementation of low-cost energy conservation techniques. However, in modern processing facilities, the heat recovered during pasteurization is up to 94% (Ramirez *et al.*, 2006a).

For shelf-stable milk, the product undergoes sterilization or ultra-high temperature (UHT) treatments rather than the milder pasteurization ones. The higher temperatures, although ensure the microbiological safety of the products at room temperature, typically require significantly more energy than pasteurized milk with the exception of indirect UHT (without direct contact with steam) that requires the same energy as pasteurization. The past two decades have seen a growing consumer demand for UHT and sterilized milk products in Europe (Ramirez *et al.*, 2006a). In France, for example, pasteurized milk comprises less than 14% of the market share of milk purchased; the remainder is UHT or sterilized milk (Ramirez *et al.*, 2006a).

For sweetened condensed milk, evaporated milk, and dried milk, pasteurized milk is concentrated by an evaporator (UNEP, 2000). To generate milk powder, the concentrate is spray-dried. The two processes – concentration and drying – are energy-intensive (Ramirez *et al.*, 2006a); thus, the production of dried milk requires 4–20 times more energy than pasteurized milk (**Table 6**). The variation in energy demand can be partly attributed to the heat-recovery capacity of the evaporators (UNEP, 2000). The type of evaporator can highly influence the evaporative efficiency – up to 7-fold – and the heat recovery and efficiency is dependent on several factors: (1) the number of evaporators in series that utilizes evaporated water from one unit as steam in the next (known as multiple effects or stages); (2) the use of vapor recompression – thermal or mechanical – to increase the pressure on the evaporated water from one unit to further elevate the heating capacity of the steam as it enters the next unit; and (3) the use of alternate technologies such as membrane filtration that require much less energy than traditional falling film evaporators (UNEP, 2000; Ramirez *et al.*, 2006a).

For canned evaporated milk, the concentrated milk is sealed in cans and sterilized by retort (UNEP, 2000). Unlike evaporated milk products, sweetened condensed milk does not undergo sterilization. Following concentration, sucrose and lactose are added to the concentrated milk which decreases the water activity and deters most microbiological growth without heat treatment (Farkye, 2009); thus, the energy demand for the production of sweetened condensed milk is less than evaporated milk (Ramirez *et al.*, 2006a).

Butter is produced from the unused cream isolated during the production of low-fat or skim milk. The cream is heated, cooled, and churned into butter (solids) and buttermilk (fluid) (Reddy, 2010). Following separation of the solids, the butter is formed, packaged, and cooled. Cultures and/or salt may also be added to the butter to generate a variety of end-products (Reddy, 2010). The most energy-demanding process during the butter production (not including milk pasteurization) is cooling (Ramirez *et al.*, 2006a).

For cheese, starter cultures are added to the cooled, pasteurized milk followed by rennet. The resulting curds and whey are cooked. Following removal of the whey, the blocks of curds are salted and molded. Depending on the processing methods, these steps comprise 7–14% of the total energy needed for cheese production and milk pasteurization accounts for 17–26% of the total energy (Xu *et al.*, 2009). If necessary, the cheese may also be maintained under controlled temperature and humidity for a specific duration – low temperatures and 90% humidity for soft cheeses and high temperatures and 75–85% humidity for hard cheeses – to develop characteristic flavors and aromas (known as ripening) (UNEP, 2000). According to Xu *et al.* (2009), ripening for more than 14 days can increase the specific energy demand by 9–65%. Generally, harder cheeses require longer ripening periods (UNEP, 2000). Thus, because of the variety of cheeses and processing methods used by cheese makers, the processing energy requirements can vary markedly (**Table 6**).

Yogurt and other fermented dairy products are produced by inoculating pasteurized milk or cream with various cultures (Vasiljevic and Shah, 2008). Numerous products are generated depending on the starting cultures utilized, the starting material (cream or milk), the extent of fermentation, and the flavor additives. Based on relative energy consumptions of dairy products, Feitz *et al.*, (2005) reported yogurt production required approximately six times more electricity and four times more fuel than pasteurized milk. In some cases, concentrated or dried milk is used along with fluid milk to produce yogurt (Gonzalez-Garcia *et al.*, 2012), which would potentially alter the total processing energy requirements because of the energy demand to produce the other concentrated milk products.

Yogurt or milk, can also be combined with other ingredients and subjected to rapid freezing to produce frozen yogurt or ice cream. Ice cream production involves many steps – preheating, mixing, pasteurization, homogenization, cooling, ageing (to stabilize the product), freezing, molding/extrusion (if necessary), and hardening – with many of the steps conducted at well below 0 °C (Korsstrom and Lampi, 2001). Although there is little data on ice cream processing, Korsstrom and Lampi (2001) reported that the energy consumption can range from 2.7 to 5.8 MJ kg^{-1} of ice cream, although they did not elaborate on how the energy values were calculated.

Flour

One of the most fundamental ingredients in baked goods (breads, cookies, cakes, etc.) is flour. Although this is typically wheat flour (Giannou *et al.*, 2003), there are a host of other flours – rice, rye, oat, and corn flour. However, for simplicity, the scope of this discussion will be wheat flour. The major step in the production of flour is milling (**Figure 1**) and consists of breaking up the grain with a series of corrugated rollers and sieves (EPA, 1995a). Before milling, the grains may be subject to drying, transport, storage, sorting/separating (to remove extraneous materials), cleaning, and tempering, which is the addition of moisture immediately before milling to facilitate the process (EPA, 1995a). The extent and necessity of grain drying is dependent on the harvest moisture content of the grain; thus, the energy demand for drying can vary by harvesting location and, even within a particular area, from year-to-year (Thompsson, 1999). Although the drying energy demands vary, Carlsson-Kanyama and Faist (2000) reported the energy requirements for grain drying to be 0.09 MJ electricity per kilogram and 0.01 kg oil per kilogram.

Using previously reported data, Thompsson (1999) generated a model of scenarios of energy efficiency within the baking industry and, in the model, the author reports milling utilizes 0.15–0.36 MJ electric energy per kilogram flour. Often milling energy demands incorporate all aspects of the production from receipt of the grain to flour production; thus, even transport mechanisms within the mill can affect the final energy demand (Thompsson, 1999). In addition, the primary energy demand for milling can vary depending on the size of the mill, according to Sundkvist *et al.* (2001). In their study of mills solely supplied by electricity, the average primary energy demands of small, medium, and industrial mills were 3.8, 0.6, and 0.9 MJ kg^{-1}. According to the Swedish LCA Food database (Nielsen *et al.*, 2003), mills that utilize both electricity and heat derived from fossil fuels, the average energy consumption is 0.3 MJ of electricity per kilogram of flour and 0.4 MJ of natural gas per kilogram of flour.

Table 7 Energy during the production of lemon, orange, and tomato juices

Product	*Process step*	*Units*	*Steam (kg kg^{-1})*	*Thermal (MJ kg^{-1})*	*Electric (MJ kg^{-1})*	*Source*

[d]Concentrated tomato juice (after RO+evaporation).

Juice

Commercial juices are the result of extracting liquids contained in fruits or vegetables and used primarily as beverages. The type of plant material used to produce juices varies by country and region of the world. The bulk of fruit juices production and commercialization are citrus – including oranges, lemons, tangerines, grapefruits, apples, and grapes; and, to a lesser extent, nectarine, peach, pears, pineapple, and berries. Of vegetables juices, tomato is produced in the greatest quantity.

The extraction process from different fruits and vegetables is generally process specific. The availability of data of energy consumptions during processing of fruit and vegetable juices is very limited; therefore this section will review only orange, lemon, and tomato juices.

Orange juice is commercialized as fresh unpasteurized, chilled (with pulp and without pulp), frozen concentrate, and canned. Lemon juice is generally commercialized as a frozen concentrate. Both oranges and lemons are citruses and the extraction processes are similar. Once transported to the processing plant, citrus fruits are first graded and washed before proceeding to juice extraction. To maintain quality, the juice is separated quickly from the peel, membrane, and seeds using extraction cups, or other methods, to prevent the extractives from contaminating the juice with bitter compounds. Then the extracted juice goes through screens to remove pulp and sacs. Further pulp removal is achieved by the finishing process. According to the literature found, extraction takes a modest amount of energy of approximately 0.03 MJ of electricity per kilogram of finished juice; and refining or finishing, about a third of that energy (Table 7). Pasteurization doubles the amount of electricity used during extraction, but also has a fairly small input of thermal energy. Concentration is by far the step that utilizes the most thermal energy. As stated by Beccali *et al.*, (2009), it takes 2.28 and 2.58 kg of steam to produce 1 kg of concentrate, which according to the same author is made with approximately 5 kg of refined juice. Assuming the service steam has a pressure of 1.37×10^5 Pa (20 psi), the enthalpy of steam at this pressure is 2.69 MJ kg^{-1}; and therefore, the thermal energy in the concentration process varies between 6 and 7 MJ kg^{-1} of concentrate. Assuming it takes approximately 3.3 MJ of fuel to deliver 1 MJ of electricity at the factory gate and an efficiency of the boiler/steam distribution system/evaporator to be approximately 80%, consumption of electricity at evaporation (compared on the basis of primary energy) is approximately 4.5 times less than thermal energy. Besides juice, citrus byproducts produce an assortment of valuable products, including energy recovery that will not be included in this discussion.

The process to produce tomato juice is different than the one for citrus. Production of tomato juice follows a similar process than other tomato products (Figure 4). There are two technologies to process tomatoes: cold break and hot break. The hot break consists of chopping the tomatoes at temperatures of 85–90 °C to deactivate pectinmethylesterases and polygalacturonases that cause degradation of pectins. In the cold break process, tomatoes are disintegrated at temperatures below 70 °C. The hot break process yields products with high viscosities which are less prone to syneresis. The cold break, however, generates a tomato paste that is thinner, but with a fresher aroma (Goodman *et al.*, 2002).

In the hot-break process, tomatoes are pumped through the hot-break system where tomatoes are heated and held to deactivate enzymes before proceeding to the juice extractor. In the cold-break system, tomatoes are crushed, heated in a heat exchanger, and then sent through the juice extractor that

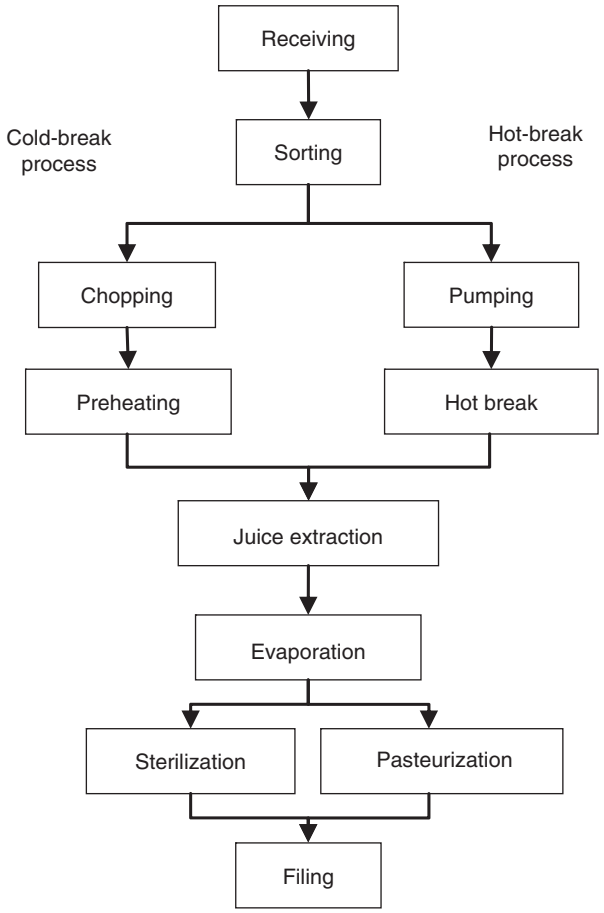

Figure 4 Tomato juice extraction process.

separates the juice from seeds, skin, and fibers. From there, the juice goes through a concentration process followed by pasteurization or sterilization and packaging. Typical values of energy consumption during tomato juice production are presented in **Table 7**.

In the data presented by Molinari *et al.* (1995), the use of reverse osmosis along with traditional evaporation techniques significantly reduces the amount of thermal energy required to concentrate tomato juice; however, the final product temperature is lower than the product of traditional evaporation, so slightly more energy is required to attain sterilization temperatures.

Meat

Meat can be obtained from virtually any animal, but the three most common sources are cattle, swine, and chicken. The basic universal processing steps in slaughterhouses consist of: (1) immobilizing and stunning the animal; (2) slaughtering and bleeding of the animal; (3) removing undesirable external parts (feathers, hide, hair, etc.); (4) decapitation; and (5) evisceration (or removal of internal organs) (IFC, 2007a; IFC, 2007b). The product of these processing steps is referred to as the dress carcass.

Although the major steps are the same in meat processing, there is some variation in the specific treatments of cattle, swine, and chicken that can affect the specific energy required for processing. Poultry carcasses, for example, are subjected to hot water treatment (50–60 °C) after bleeding to facilitate feather removal (Finnish Environment Institute, 2002) with lower temperatures ('soft-scalding') used for products to be chilled and higher temperatures ('hard-scalding') used for products to be frozen (Ramirez *et al.*, 2006b). Ramirez *et al.* (2006b) estimated that the difference in energy demand for the techniques is approximately 0.08 MJ kg^{-1}. Similar to poultry, pigs are also subjected to scalding (followed by mechanical or water abrasion) to facilitate the removal of hair; however, the process is not comprehensive and pigs require an additional hair removal treatment (Finnish Environment Institute, 2002). This involves the carcass being placed briefly in an oven (held at 900–1000 °C) to singe the persistent hairs as well as reduce the microbial load and alter the skin texture (IFC, 2007a; European Commission, 2005). In addition, if bacon is the desired end-product, the singeing is more extensive and the product requires additional treatments to generate a polished skin (or rind) (IFC, 2007a; European Commission, 2005). Owing to these heat treatments, the specific thermal energy requirements for pork processing tend to be greater than chicken and beef; however, the specific electricity (and total primary energy) requirements for chicken processing are greater than the beef and pork (**Table 8**).

The end-products of meat processing facilities are highly varied and, consequently, so are the energy requirements for processing (**Table 8**). The facilities may also debone, cut, grind, cook, dehydrate, sterilize/pasteurize, smoke, chill, or freeze the meat (European Commission, 2006; IFC, 2007a). Cutting and deboning can require an additional 0.76 MJ kg^{-1} of dressed carcass (primary energy) (Ramirez *et al.*, 2006b). For the production of hamburgers, Carlsson-Kanyama and Faist (2000) reported that grinding and frying the ground beef requires an additional 0.3 and 5.1 MJ of electricity per kilogram of product, respectively. Similarly, because of the extensive processing (compared to raw meats), sausages and salami require significantly greater processing energy than other meat products (**Table 8**).

The energy demand of these processes can also be affected by the types of meat. For example, the additional energy required to freeze meat after the initial processing is dependent on the type of carcass (in primary energy): beef, veal, or sheep requires 0.72 MJ per kilogram of product; pork requires 1.0 MJ kg^{-1} of product; and poultry requires 1.2–2.4 MJ kg^{-1} of product. The higher specific energy demands for poultry are attributed to the additional energy required for the hard scalding treatment, a prerequisite of frozen poultry (Ramirez *et al.*, 2006b).

According to the Finnish Environment Institute (2002), however, the heat recovery potential in slaughterhouses can be up to 0.21, 0.43, and 0.79 MJ kg^{-1} for cattle, pig, and poultry, respectively. In addition, the implementation of steam (or spray scalding) can potentially conserve energy in pork processing (European Commission, 2005) as well as reduce microbial cross-contamination in poultry processing (IFC, 2007b).

Oils

Oils are lipid-rich extracts derived from diverse sources including seeds, nuts, fruits, and legumes. The oil is derived from milling – sorting and cleaning, removing husks, and crushing – and extraction from the source. Before extraction, the milled plant material may also be subject to conditioning (heating) to facilitate the extraction process (Brown *et al.*, 1996; Schmidt, 2007). Extraction can be solely mechanical (pressing), physical (boiling/heating), or chemical (by the addition and subsequent removal of hexane) or involve a combination of three processes (European Commission, 2006; IFC, 2007c; Schmidt, 2007). In addition, for many oils, a refining step is necessary. Refining is a multistep process which can vary depending on the oil and the use of physical or chemical techniques (IFC, 2007c). Degumming, neutralization, soap splitting, bleaching, deodorization, and hardening are the major steps involved in refining oils (IFC, 2007c; European Commission, 2006).

The processing for each type of oil can be widely varied, so energy consumption can vary considerably as well. In addition, reported energy consumption depends on how the values were obtained: by direct measurement or estimated with databases. Data presented in **Table 9** comes mainly from LCAs conducted by different authors using data from databases.

Soybean, rapeseed, and sunflower oils have similar extraction processes using hexane; and energy intensities to produce these oils are in the same order or magnitude. Traditional palm oil and kernel oil extraction have lower overall energy consumption than oils obtained with solvent extraction, because they use mechanical extraction and recovery of energy. The net energy consumption of palm oil extraction is fairly low, whereas the gross thermal energy consumption is high (**Table 9**). The reason for the difference is that many palm oil mills obtain most or all of the processing steam and electricity from the incineration of palm shells. In addition, palm kernels are a byproduct of milling during palm oil production (Schmidt, 2007). As a result, palm kernel oil production generally does not require as much energy as other oils.

Data for olive oil are limited and the lowest estimate is approximately 10 times less than the highest, which could be indicative of the difference in processes, estimation methods, and the inclusion or not of the refining step. Sources do not specify if the values correspond to net energy consumed or expressed as primary energy.

Rice

Once harvested, rice is either dried on site or transported to commercial dryers (**Figure 5**). At harvest, rice moisture content is too high to make it stable for long term storage; therefore, its moisture content needs to be lowered to approximately 13% to preserve its quality and safety (Howell and Cogburn, 2004). Drying is the most energy intensive operation during rice processing. It accounts for approximately 55% of the total energy used from farm production to finished product. Of the

Figure 5 Production of milled rice. Adapted from Kasmapraphruet, S., Paengjuntuek, W., Saikhwan, P., Phungrassami, H., 2009. Life cycle assessment of milled rice production: Case study in Thailand. European Journal of Scientific Research 30 (2), 195–203.

remaining 45%, 15% goes to harvesting, 10% to cultivation, 10% to seeding, 6% to transportation, and 4% to milling (Kasmapraphruet *et al.*, 2009).

Energy use during drying varies significantly according to the type and variety of grain, type of dryer, drying temperature, relative humidity, initial moisture content, and final moisture content, among the most important factors. In the case of rice, initial moisture content also affects the head rice yield (HRY), which is the mass percentage of kernels that after milling have a length of 75% or more of the original length (Cooper and Siebenmorgen, 2007). Typical harvest moisture contents range from 20% to 30%, depending on the extent of rain (Bergqvist *et al.*, 2008); but in a study conducted in Arkansas, Bautista and Siebenmorgen (2009) found that the optimal harvest moisture content that maximizes HRY is 18.2–21.6% for long-grain varieties, 19.0–20.4% for medium grain cultivars, and 17.7–19.0% for the long-grain hybrid 'XL723.' According to Gunasekaran and Thompson (1986) energy to dry crops can vary between 3 and 8 MJ kg^{-1} of water removed. Specifically for rice, a recent study conducted on cross-flow dryers showed that the thermal energy required to dry rice ranged from 6.9 to 9.7 MJ kg^{-1} of water removed (Billiris, 2013).

As indicated by different authors, energy requirements for rice milling are at least one order of magnitude (10 times) less than the thermal requirements to dry (**Table 10**). Milling is the operation to transform rough unprocessed rice into white or brown rice. In **Table 10**, the average energy intensity of milling is approximately 55% more when expressed on the basis of paddy (rough rice, or unprocessed rice kernels) than of finished rice. The opposite would be expected because it takes approximately 1.5 kg of paddy (depending on the HRY) to produce 1 kg of rice. However, most sources do not report the HRY, which makes difficult to establish a fair comparison. In addition, energy use during milling depends on the degree of milling, which is the extent of removal or bran and germ from the kernel during milling (Cooper and Siebenmorgen, 2007). In a study conducted in Japan, DOM of 2, 5, and 10% required electricity intensities of 0.30, 0.38, and 0.96 MJ kg^{-1} of finished rice, respectively (Roy *et al.*, 2009).

Parboiling is a technique used around the world, but it is especially important in the developing countries of Asia. Parboiling consist of partially boiling the dry paddy while it is still in the husk, followed by drying, dehusking, and milling (Roy *et al.*, 2007). Data for rice parboiling in India and Bangladesh are presented in **Table 11**. Before milling, the parboiled paddy must be dried to 14–16% (Kapur *et al.*, 1997). This is particularly important because the moisture content of parboiled rice is typically in excess of 30% (Kapur *et al.*, 1997). Drying can be conducted via direct solar radiation to mitigate some of the energy requirements (Ahiduzzaman and Islam, 2009). Owing to hardening of the husk after parboiling, milling of parboiled rice requires more energy than rough rice (Borah and Prasad, 1994; Kapur *et al.*, 1997). Rice husk can be utilized as a source of energy – typically thermal energy although use as an electric energy source has been explored (Kapur *et al.*,

1997). Approximately 0.1 kg rice husk is generated by 1 kg rice (Kasmapapruet *et al.*, 2009) and the energy density of rice husk is 11.7–15.1 MJ kg^{-1} (Bureau of Energy Efficiency (BEE) India, 2010).

Sugar

Table sugar, or sucrose, is saccharose obtained commercially from beets and sugarcane. Sugarcane is grown in tropical and semitropical parts of the world, whereas beets belong to colder climates. In the US and Europe, beets are almost the exclusive sources of sucrose. In the UK, for example, 60% of the sugar is obtained from sugar beet, whereas the remaining sugar (from sugarcane) is imported (Vaccari *et al.*, 2005). In addition to beets, the US also produces sugarcane in the states of Florida, Louisiana, Texas, and Hawaii. In the US, there is also direct competition for sucrose from sweeteners obtained from corn. According to data from 2004, of the 45 kg consumption of sweeteners per capita in the US, approximately 60% were sweeteners from corn and the remainder was table sugar (Haley *et al.*, 2005).

One of the first steps in sugar production is the extraction of sugary juices from the plant material. Sugarcane is crushed and the juice separated from the bagasse, which is burned in boilers. According to Ramjeawon (2004), after sugar processing, there is a surplus of approximately 0.2 MJ of energy per kilogram of sugarcane from burning bagasse. The juice goes through a clarification process and then through evaporators to concentrate the clear juice into sugar liquor. Crystallizers then transform the sugar liquor into crystals that are separated with a centrifuge and dried to become raw sugar. Beets, however, are sliced and passed though a diffuser where sugar is extracted with water to produce a raw juice that then goes through similar steps as sugarcane.

Raw sugar can be used as is, but it is more commonly transported to sugar refineries to produce refined sugars. Many sugar mills produce straight refined sugar by cleaning up the concentrated liquor before the crystallization step.

Data on energy consumption of sugar production is limited and variable (**Table 12**), which makes generalizations challenging. In addition, the literature describes the use of thermal energy in many different ways – thermal, steam, hot water, and fuel – without specifying how the different forms of energy are transformed into each other. Because the process of raw sugar production requires phase changes (e.g., evaporation and crystallization), the need for thermal energy surpasses electricity by at least one order of magnitude. According to data for cane sugar, the refining process takes much less energy than production of raw sugar, but still requires more thermal energy than electricity.

Greenhouse Gas Footprint

There are natural greenhouses – carbon dioxide (CO_2), water vapor, methane (CH_4), and nitrous oxide (N_2O) – and man-made ones – HFCs, perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6). All these gases are directly or indirectly emitted

by food processing plants as a result of energy produced and acquired, use of fossil fuels, refrigeration equipment, materials used in the process, waste treatment, and other sources.

The levels of GHGs emitted by food processing plants depend on the degree of processing, the products, and the type of processing. As a generalization, the more extensive the processing, the more GHGs are produced at the processing stage, but it also reduces emissions at the consumption stage. For instance, with ready-to-eat products, the emissions of food preparation from households are transferred to the processing stage and vice versa for products that require less processing.

The type of processing dictates the type of greenhouse gas emissions. Freezing and refrigeration emissions are the result of energy consumption and fugitive emissions of refrigerants – HFCs. Processing by application of thermal energy – blanching, pasteurization, sterilization, evaporation, extrusion, drying, baking and roasting, and frying – emits mainly carbon dioxide from the combustion of fossil fuels. Emissions from mechanical processes (including electric motors) come from purchased or generated electricity. The type of packaging also influences emissions not only from the production of the package itself, but also from the production of the packaging materials. Embedded emissions of carbon dioxide and the perfluorocarbons CF_4 and C_2F_6 are common during aluminum packaging production; and embedded emissions of carbon dioxide are generated during paper, steel, and plastic packaging production.

Greenhouse Gases Emissions Inventory

A GHGs inventory is a computation of GHGs emitted to and removed from the atmosphere over a period of time. The inventory includes the six major GHGs – CO_2, CH_4, N_2O, HFCs, PFCs, and SF_6.

There are protocols to conduct GHGs inventories, but the one created by the Greenhouse Gas Protocol Initiative (GHG Protocol, 2004) is the most commonly followed. The GHG protocol divides emissions in two broad groups: direct and indirect. Direct emissions are GHGs generated by sources controlled by the reporting company; and indirect emissions are those resulting from activities developed by the reporting company, but they happen in facilities owned or controlled by another entity. To make a more accurate computation of GHGs emissions, the GHG protocol categorizes direct and indirect emissions in three broad scopes (GHG Protocol, 2004):

Scope I: Direct emissions from stationary and mobile sources owned or controlled by the entity, such as on-site generation of electricity, fuel burned by boilers, fugitive emissions from equipment (e.g., refrigeration equipment), on-site wastewater treatment, on-site solid waste treatment, vehicles, equipment, etc.
Scope II: Indirect emissions from purchased electricity, steam, and other energy sources.
Scope III: Other indirect emissions from sources that are not owned or controlled by the entity and are not included in Scope II, for instance employee commuting and traveling, services outsourced by the entity, such as off-site wastewater treatment and solid waste disposal.

The GHG Protocol (2004) prescribes the following sequence of steps to conduct the inventory: (1) defining the business goals of the inventory; (2) setting the organizational boundaries to identify the operations controlled by the company; (3) setting operational boundaries to identify the emissions related with each operation and their

Table 13 Emission factors for the combustion of selected fuels

	kg CO_2 per ton	*g CH_4 per ton*	*g N_2O per ton*

characterization as direct or indirect emissions; (4) tracking emissions over time, which consist of choosing a base year and then recalculating base year emissions based on structural changes, such as mergers, acquisitions, outsourcing, insourcing, etc.; (5) identifying and calculating GHG emissions and converting the emissions into CO_2-equivalents; (6) reporting according to the accounting principles of relevance, completeness, consistency, transparency, and accuracy; and (7) verification, which is an optional step conducted by a third-party auditor.

Greenhouse Gases Emissions Inventory

Because carbon dioxide is not the only greenhouse gas and considering that all GHGs have different global warming potentials, a way to standardize emissions for the purpose of accounting is to use the concept of carbon dioxide equivalent, CO_2-eq. Using this approach, the global warming potential (GWP) of different gases are expressed relative to carbon dioxide, which is assigned the value of 1. So, for instance, the GWP of methane for a 100-year horizon is 21. This means its GWP is 21 times more powerful than carbon dioxide. Global warming potentials relative to CO_2 are calculated using different horizons, typically 20, 100, 500 years, with the 100-year horizon generally used for GHG emission inventories.

Based on the standardization just described, the GHG emissions expressed as CO_2-eq for a particular gas (i) is calculated as:

$$\text{GHG emissions in } CO_2\text{–eq}_{(i)} = \text{emission factor}_{(i)} \times \text{activity rate} \times \text{GWP}_{(i)}$$

Glossary

Cash flow budget A projection of the expected cash inflows and cash outflows for a business over a period of time.
Enterprise budget A projection of all the costs and returns for a single enterprise.
Liquidity The ability of a business to meet its financial obligations as they come due.
Operating cost Cost for the purchase of inputs and services used up relatively quickly, usually in one production cycle.
Opportunity cost Income that could be received by employing a resource in its most profitable alternative use.
Ownership cost Cost that results from owning an asset, regardless of how much it is used.
Partial budget An estimate of the changes in income and expenses that would result from carrying out a proposed change in the current farm plan.
Profitability The degree to which the value of a set of agricultural products exceeds the cost of the resources used to produce them.
Solvency The degree to which the liabilities of a business are backed up by its assets.
Whole farm budget A projection of the total income and expenses of a farm business over a certain time period.

Introduction

Farm management in the broad sense means making decisions on activities that ultimately produce plants and animals that can be used for food, fiber, and/or fuel. The end goal may be to use the products personally, or to sell them for cash. The farm manager must decide what to grow, how much to grow, how to grow it, how to sell it, and how to obtain resources to produce it.

Unique Decision-Making Environment

Farm managers and managers of other businesses make similar decisions. However, agriculture has some unique aspects that affect how farm management decisions are made.

Biological processes and weather

The laws of nature place some severe limitations on what a farm manager can accomplish. Crops require certain nutrients, including water, that may be in short supply. They require some minimum length of time to reach maturity and certain hours of daylight. Livestock can only consume a limited quantity of feed each day, and reproduce according to their biological schedules. Even attempts to control the effects of climate through irrigation of crops and confinement of livestock can be thwarted by sudden rainstorms, blizzards, and other natural events. The unpredictability of the production process is a significant concern in agriculture, far more than in most other industries. Weather, genetics, and disease all introduce elements of risk that most nonfarm businesses do not face.

Fixed supply of land

At least in the more developed countries of the world, nearly all the arable land is already under production. Other industries can buy more raw materials or replicate production facilities, but for many farm managers the supply of land is essentially fixed. How to gain access to land is a crucial management decision, and the price of farmland is often very sensitive to current economic conditions.

Small size of business

Approximately 58% of the farms in the United States have only one operator. A similar pattern holds true in much of the rest of the world. Even in countries where very large private or publicly owned farming operations have been tried, families engaged in farming still prefer to have their own enterprises. As a result, the roles of owner, worker, and manager are commonly filled by the same individuals.

 doi:10.1016/B978-0-444-52512-3.00111-X

Perfect competition

In an industry with many small firms, no one business can significantly affect the prices at which products are sold or inputs are purchased. Moreover, agricultural products are often homogeneous, meaning that one producer's output may be essentially identical to the output of any other. In such cases, prices are determined by national, and even international, supply and demand conditions, which are often unpredictable. The farm manager must react quickly when conditions change. Achieving high rates of production efficiency and controlling costs are keys to managing a profitable business in this economic environment in a competitive industry.

Important Farm Management Issues in the Twenty-First Century

Advances in technology

Agricultural technology has been evolving for many centuries and will very likely continue to do so. Selective retention of the best species of animals and the best grain seeds has long allowed farmers to improve productivity. Scientific breeding based on genetic principles has served to accelerate this improvement in productivity. In recent years, biotechnology has been used to introduce useful genes into existing species. Crop varieties have been engineered to fit growing conditions at particular locations, to be resistant to certain herbicides and insects, and to have more desirable traits such as higher oil or protein content. New nonfood uses for crops, such as biofuels, will open new markets but also may change the desired composition of plants grown for specific uses.

One example of a recent technological change is the use of global positioning systems (GPS) to pinpoint exact locations in a field. Early uses of GPS allowed farmers to collect very precise data about crop yields, moisture, and incidence of pests. Applications of fertilizer, pesticides, and irrigation water can be modified to fit very small areas, improving the efficiency with which these resources are used. GPS can also be used to steer machinery, resulting in less overlapping application of crop inputs and less operator fatigue.

Information management

Farm managers have long kept accounts of production, expenses, and sales, historically in hand-written record books, but analyzing the resulting data was often a tedious chore. Several decades ago home computers were adapted for farm record keeping. The ability to collect information has increased tremendously in recent years, through the use of electronic sensors and wireless transmission of data. As a result, farm managers have more information available to them, and can process and summarize it more quickly. Sensors can be combined with automatic controls to continuously monitor temperature and humidity in livestock buildings, the cleanliness of grain being harvested, and the degree of moisture in the soil, and other conditions so that adjustments can be made quickly.

Financial transactions can now be made without the need to exchange cash or checks. The use of bar codes and debit or credit cards allows financial information to be sent to a central location instantly, so financial accounts can always be up to date, and transaction data can be easily stored for later access.

In previous eras, farm managers were frustrated by a lack of current and complete information with which to make timely decisions. Today, managers can be overwhelmed by the sheer volume of data available. A vital task of farm management today is to determine which information is critical to decision making, which information is merely interesting, and which information is not relevant.

Controlling assets

Not all farm assets have to be owned. Farm management relies on combining land, labor, and capital to produce crops and livestock efficiently. However, land may be rented, labor may be hired, and capital may be borrowed. Agriculture has long relied on both traditional and innovative land tenure systems in which joint ventures between landowners and farm operators have been mutually beneficial. Leases may call for a cash payment to the landowner, or some negotiated sharing of production.

Agricultural production often involves a considerable investment in seed, fuel, fertilizer, feed, and other inputs before any production is available to sell. Farm managers must depend on banks and other financial institutions to supply credit until revenues are realized. Using the proper mix of debt and equity capital can have a large impact on the long-term viability of the farm business.

Meeting consumer demands

Although agriculture has long been characterized by undifferentiated commodities and prices determined in national or global markets, increased concern with nutrition and food safety coupled with improved capability to measure the desired characteristics of agricultural products has made it possible to achieve higher selling prices by producing to meet consumers' tastes. Niche markets for organically produced food, lean meat, and specialty fruits and vegetables provide profit opportunities for the skilled producer. The trend toward more free trade among nations is expanding the number and variety of markets available to farmers and ranchers.

Environmental and climate concerns

Agricultural production has always involved the exploitation of resources such as soil, water, and energy. Increasing production to feed a growing world population while at the same time conserving resources for future generations has led to a search for 'sustainable' agricultural methods. Farm managers must take a long-term view when making decisions about which technologies to follow and what commodities to produce while still generating sufficient profits in the short run to earn a living. Farm managers must also be aware of possible trends in climatic conditions, and learn how to adapt their production methods accordingly.

Planning

Farm management can be divided into three sequential phases: planning, implementation, and evaluation. Most farm managers carry out all three functions at the same time, although the season of the year may affect which one gets the

most attention. And once the cycle has been completed, it typically starts all over again.

Planning involves looking ahead and anticipating what decisions have to be made and what information will be needed to make them. Planning can be strategic (deciding what the farm should do) or tactical (deciding how to do it).

Strategic Planning

Mission

Strategic planning starts with defining the mission of the business. A mission statement is a short summary of why the business exists. Because many farm businesses are operated by a single family, mission statements often reflect personal values and priorities as well as business considerations. An example of a mission statement for a farm could be: "Our mission is to produce safe and nutritious products and earn sufficient profit to continue operating, while maintaining and enhancing the quality of the land and water resources under our control to ensure long-term viability."

Goal setting

Goals serve as a reference point for making management decisions and measuring progress over time. The goals formulated by individual managers will depend on their values. Some managers value financial success and constant expansion of the business. Others desire a balance between work, leisure, and family time. Still others have a strong conservation ethic, and emphasize preserving resources for future generations.

To be effective, goals should be as specific as possible, with measurable levels of achievement, and a timetable for reaching those levels. An example would be a goal "to own 100 ha of class A farmland in Washington County within ten years" or "to pay off 10 percent of the operation's total debt within five years." Most farm managers have multiple goals, so they need to set priorities among them before they can become useful yardsticks for making decisions.

Internal scanning

Good farm managers also need to assess the strengths and weaknesses of the farm business. These strengths and weaknesses may be related to the physical resources, such as soil type, availability of water, drainage capability, uses for existing buildings, existence of perennial crops, and area of land controlled. The number of workers available and their individual skills will impact what enterprises are feasible. The financial resources of the business will determine if new enterprises can be considered and what risk management measures are necessary. A thorough and realistic assessment of the farm's physical, human, and financial resources will identify possible new enterprises and activities while eliminating those that have little chance for success.

External scanning

Critically surveying the social and economic environment in which the farm operates will increase the chances of reaching the goals set by the manager. Recognizing trends in consumer tastes, evaluating new technologies, and keeping updated about shifting supply and demand factors for products as well as for resources will allow the farm to remain competitive in the long run. Public policies will also affect a farm's competitive position. Macroeconomic policies lead to changes in interest rates, foreign exchange rates, availability of credit, and rates of inflation. Certain government programs may set a safety net under farm income or prices of specific commodities, impose regulations or subsidize farming practices that are friendly to the environment, give favorable treatment to underserved classes of producers or beginning farmers, or favor production of certain commodities such as biofuels.

Identifying strategies

After assessing both the internal resources and the external conditions, the manager must identify alternative strategies for achieving the previously specified goals. This stage is often called strategic management. Often more than one strategy is feasible, but some may be rejected as too risky or not timely. Several tools for evaluating alternative actions will be discussed later.

Implementation

Once a strategy is chosen, the manager must take the necessary steps to carry it out. In some cases a business plan will be formulated and presented to lenders, landlords, or partners in order to acquire the resources necessary to implement the strategy. The short-term decisions needed to carry a strategy through to completion are collectively called tactical management.

Evaluation

After a strategy is fully implemented, the manager must judge whether it has been successful based on the original goals that were formulated. Accurate assessment will require collection and interpretation of appropriate information. Useful tools for evaluation will be discussed later. Strategies should be monitored over time in case some internal or external conditions change and the strategy must be altered or abandoned. Many production processes in agriculture are repeated annually or more often, so evaluation should be completed before the next cycle begins.

Cost Concepts

Both planning and evaluation require a basic understanding of how to identify costs and returns related to each alternative strategy or action being considered or undertaken. Costs, in particular, have different management implications.

Ownership costs

Some costs arise simply from owning productive farm assets, regardless of how much they are used. Depreciation is the loss in value over time for assets such as machinery, equipment, and buildings due to age, wear and tear, and obsolescence. Depreciation can also be an accounting entry by which the initial investment outlay for an asset with a useful life of more than 1 year is allocated over the period for which it is owned. Note that land is one long-lived asset in agriculture that is not

depreciated because it is assumed to maintain its productivity indefinitely if managed wisely.

Interest represents the cost of having capital tied up in long-term assets, including land as well as depreciable assets. Interest can be the cost of borrowing funds from a lender, or the income foregone by investing the farmer's own capital in a farm asset rather than some other income-producing investment.

Other ownership costs can include insurance against theft or casualty, property taxes, and routine maintenance costs that are not related to degree of use.

Ownership costs are often referred to as fixed costs. Once an asset is purchased, the ownership costs are fixed in value, and do not vary according to how much the asset is used. Even if the asset is not used at all, the fixed costs still occur. It can be argued that assets such as machinery and buildings will depreciate more as their annual use increases. Nevertheless, the usual accounting convention is to base depreciation solely on age or years of ownership.

Operating costs

Operating costs occur only if an asset is actually used, and in direct proportion to its degree of use. Examples include fuel and repairs for machinery, electricity for buildings, and gas for drying grain. In addition, some inputs such as seed, feed, fertilizer, medicines, and pesticides are fully used in one production cycle and are thus also included in operating costs. Operating costs are sometimes referred to as variable costs, because in contrast to fixed costs they vary in direct proportion to the number of units of the enterprise produced.

Opportunity costs

Costs that involve a direct monetary outlay are called cash costs. They are the most visible type of cost, and typically represent a large proportion of total costs. However, some costs arise from using certain assets in the farm business rather than in some other capacity. These costs are called opportunity costs. The value of foregone interest from using the owner's own capital to purchase farm assets or supplies instead of placing it in some other investment has been mentioned. Most farm operators also have an opportunity cost for using their own labor on the farm instead of earning a wage elsewhere. Small farms under a sole proprietorship form of business typically do not provide a cash wage to their operators, but the operators' labor still has an imputed value. Other opportunity costs found in farming may include the value of raised crops that are fed to livestock rather than sold off the farm, or produce consumed by the farm family itself.

Budgeting

Expected costs as well as expected income from farming can be arranged in a particular format called a budget. Several types of budgets are commonly used in farm management, and each one has its own special purpose.

Enterprise budgets

A complete list of all expected costs and revenues associated with producing one unit of a particular type of crop or livestock is called an enterprise budget. The first step in developing a budget of this type is to define the enterprise. It can be the production of a common crop, such as rice, corn, wheat, or tomatoes, or it can be more specific, such as producing yellow corn, white corn, sweet corn, seed corn, or high-starch corn. Livestock enterprises can be the complete production of common types of livestock, such as beef cattle, dairy cattle, sheep, goats, poultry, or swine, from birth to market, or for only a specific life phase such as breeding, development, or finishing (Table 1).

The 'budgeting unit' is usually some measure of land area for crops, such as one hectare or one acre. For livestock the budgeting unit is often one head (i.e., one animal), but breeding budgets can also be developed for one litter of pigs, one batch of birds in a poultry house, or one cow unit, which includes not only the cow but also a certain percentage of a bull, a calf, and a replacement heifer, based on the relative proportion of each type of animal in a typical herd. Livestock enterprise budgets may also be based on a certain number of animals, such as 100 cows.

Enterprise budgets usually list the amount of product that is expected to be produced. For crops this is usually the yield per land unit, such as bushels per acre or tonnes per hectare. Some crops may produce more than one product. An example would be wheat, which produces both grain and straw. For each product an expected selling price is shown. Prices can be based on historical information or on current bid prices for future delivery, sometimes known as futures prices or forward contract prices. The expected volume of product multiplied by its selling price is known as the gross revenue (also called total revenue or gross income). The same units should be used for estimating the quantity to be sold and the price, such as kilograms and dollar per kilogram.

Variable or operating costs are generally listed next. They are usually estimated by specifying the quantity of a certain input that will be used for each unit of the enterprise carried out, such as seed or feed, and then multiplying that quantity by the expected purchase cost per unit. Again, it is critical that the quantity to be used and the purchase price are based on the same unit of measure. Some variable costs may be expressed simply as a cost per unit of enterprise, based on historical data, when the quantity to be used cannot easily be specified in other units. One example would be veterinary services for livestock, and another could be insurance per acre of a crop.

Fixed or ownership costs are usually listed at the end. Depreciation, interest, taxes, and insurance have already been mentioned. These can be applied to buildings and storage structures as well as to machinery and equipment. The cost for land can be expressed in several ways. If the land is rented, the value of the rent to be paid can be shown. Land that is owned by the farmer can be valued based on interest cost, either cash or opportunity or some combination, or the opportunity cost of not renting the land to another farmer. Other land costs such as real estate taxes and maintenance of fences, water lines, and irrigation systems should also be included.

Totals for both variable and fixed costs are usually shown within the budget, as well as the sum of all costs. The value of gross revenue minus variable costs is called gross margin, or income over variable costs. When gross margin is positive, that is, when expected revenue is greater than expected variable

Table 1 Enterprise budget example

Item	*Unit*	*Quantity*	*Price*	*Amount ($)*
Revenue				
Wheat grain	Tonne	3.0	$300.00	900.00
Total revenue				900.00
Operating expenses				
Seed	kg	100	$0.42	42.00
Fertilizer: Nitrogen	kg	65	1.00	65.00
Phosphorous	kg	35	1.32	46.20
Potash	kg	25	1.20	30.00
Herbicide	liter	0.9	15.00	13.50
Fuel, oil, lubrication	hectare	1	61.25	61.25
Machinery repairs	hectare	1	41.00	41.00
Labor	hour	3.75	14.00	52.50
Interest (operating expenses for 6 months)	$	$335.20	3%	10.54
Total operating expense				361.99
Gross margin (total revenue minus variable costs)				538.01
Ownership expenses				
Machinery depreciation	hectare	1	60.50	60.50
Machinery interest	hectare	1	51.50	51.50
Machinery taxes and insurance	hectare	1	6.25	6.25
Land charge	hectare	1	300.00	300.00
Miscellaneous overhead	hectare	1	16.00	16.00
Total ownership expenses				434.25
Total expense				796.24
Profit and return to management				103.76

costs, it will pay the farmer to go ahead and produce the enterprise in the short run. Even if the gross margin is not sufficient to cover all the fixed costs, the farm will be better off by producing. If no production took place, the fixed costs would still exist, so earning enough to pay for part of the fixed costs is better than the alternative.

Expected gross revenue minus total costs is called profit. Sometimes the term 'return to management' is used instead, because the value of the farmer's management time and ability is usually not included as an explicit cost. In some cases a total cost per unit of production sold is shown. This is computed by dividing the total costs by the number of units of the product that will be sold. When more than one product will be available to sell, the expected income from the less important products should be subtracted from total costs before they are divided by the units of the main product to be sold. This value is also called the breakeven price, and can be used as a benchmark by the farmer for making marketing decisions.

A similar process can be used to calculate a breakeven yield for the principal product. The budgeted total cost, minus expected income from secondary sources, is divided by the expected selling price of the primary product to find the minimum yield or quantity needed to pay the total costs of production.

An enterprise budget implicitly defines the package of technology the farmer has decided to employ to produce that particular product. The technology is embedded in the type and quantity of each input listed.

Enterprise budgets can be used to judge in advance whether it will be profitable to produce a certain enterprise. They can also be used to compare the profitability of several alternative enterprises. Finally, they can be used as building blocks for other types of farm budgets.

Whole farm budgets

Most farm businesses consist of more than one land unit of a crop or one head of a livestock specie. Indeed, many of them produce multiple enterprises on a large scale. Thus, it is useful to produce a budget showing all the enterprises on the farm combined, each aggregated to the actual number of units to be carried out. This aggregated budget is called a whole farm budget.

A whole farm budget must be first based on a whole farm plan. This plan includes a list of all proposed enterprises and the amount of each. It should be derived from a careful process of internal and external scanning, as described in the Sections Internal scanning and External scanning. It may be modified based on expected product and input prices for the upcoming production cycle.

Once the plan is chosen, the costs and returns from each enterprise budget can be multiplied by the number of projected units of that enterprise, and the results summed. The same structure of gross revenue, variable costs, fixed costs, and profit can be followed. Expected revenue from other sources besides the budgeted enterprises can be added to the enterprise revenue. Additional revenues could come from performing custom machinery services for other farmers or participating in certain government commodity programs.

Sometimes it is more logical to omit fixed costs from the enterprise budgets and simply add them into the whole farm budget. Many fixed costs do not vary directly with the number

of units of each enterprise that the farm plans to carry out, but are a set value. Examples are wages for a full-time hired employee, premium costs for liability and property insurance, payments for services such as bookkeeping and tax preparation, and depreciation on buildings.

Total revenue minus total costs is equal to expected profit at the farm level. Sometimes an intermediate value is calculated, called net farm income. It is equal to total revenue minus all costs except the opportunity costs of the farmer's own capital and labor. Net farm income is sometimes referred to as a return to equity capital, operator labor, and management.

Whole farm budgets can be created for both a short-term and a long-term planning horizon. A short-term budget usually reflects expected prices, yields, and costs for the next year or next production cycle. Values chosen will depend on near-term price forecasts and weather conditions. A long-run budget, however, will be based on average values observed over several years, perhaps modified for any trends that are expected to impact conditions during the farmer's planning horizon.

The best sources of data for both enterprise budgets and whole farm budgets are actual results from the same farm during recent years. Keeping accurate and complete records of crop yields, livestock production levels, rates of inputs used, and selling prices will provide reliable estimates for the next budgeting cycle. Of course, some budgets may include enterprises or technologies that have not been tried on the particular farm in question. In that case, records or observations of results obtained on nearby farms or experiment stations can be used.

Although a whole farm budget can summarize the expected revenue and costs for a particular mix of enterprises, it does not guarantee that this mix will maximize the profit potential of the farm. A series of comparative budgets can be prepared, each one based on different enterprises or a different number of units of the planned enterprises. Some plans may include added resources such as more land, additional labor, or new livestock facilities. The various budgets can be compared based on expected profit, riskiness, and environmental impact.

When many combinations and levels of enterprises are possible, a mathematical process called linear programming (LP) can be used to identify the farm plan that will maximize total profit or some other objective. The LP model must specify the objective to be maximized; the supplies of fixed resources such as land, labor, and capital that are available; the set of possible enterprises or activities; the quantity of each fixed resource that one unit of each enterprise requires; and the expected contribution of each enterprise unit toward the objective, for example, total profit. The LP solution will list the number of units of each enterprise that should be carried out in order to maximize the objective, as well as the value of adding one more unit of each fixed resource and the penalty for producing one unit of an enterprise not in the optimal solution. To be a useful tool, the LP model must be accurately specified; otherwise, results will not be reliable.

Partial budgets

Sometimes farm managers contemplate making changes that will affect one production practice, but will not alter other aspects of the farm. In such cases a partial budget can be prepared. A partial budget analyzes only the costs and revenues that would be changed as a result of some other change in the overall farm plan. Costs and revenues that would stay the same can be ignored, saving time and effort that would be needed to estimate them.

The first step in a partial budget is to define the change that is being considered. Only one change should be analyzed at a time, so that the effects of that particular change are clear. Second, all the potential changes in input use, costs of production, output levels, or selling prices should be listed. These can be categorized into four classes: added revenues, reduced costs, reduced revenues, and added costs. Once each projected change has been identified, a monetary value can be attached to it, using the best short-term or long-term price projections available. Finally, the added or reduced costs and revenues can be summed to find the expected net change in profit. The general equation is:

$$\text{Added revenues} + \text{reduced costs} - \text{reduced revenues} - \text{added costs} = \text{change in profit}.$$

A partial budget can be developed for one unit of an enterprise if the changes being contemplated would not affect the size of the enterprise or any other enterprises. More often, though, the changes will need to be budgeted at the level of the whole farm business (Table 2).

Sometimes it is useful to calculate the value of a certain key variable for which the net change in expected profit would be exactly zero. This is known as a breakeven value. Any variable can be chosen, but only one breakeven value can be calculated

Table 2 Partial budget example

Decision: Sell corn as standing silage instead of harvested grain (1 ha)			
Additional revenue		Additional costs	
Sell 25 tonne of silage @ $110	$2750	Phosphorus fertilizer: 36 kg @ $1.25	$45
		Potash fertilizer: 140 kg @ $1.10	$154
			$199
Reduced costs		Reduced revenue	
Harvesting grain	$85	Sell 10 tonne of corn grain @ $220	$2200
Hauling grain	$20		
Drying grain	$65		
	$170		
Net change in profit = $2750 + $170 − $199 − $2200 = + $521			

Table 3 Cash flow budget format

	Period 1	*Period 2*	*Period 3*	*Period 4*
a. Operating income				
b. Capital asset sales				
c. New loans to receive				
d. Total cash inflows (a+b+c)				
e. Operating expenses				
f. Capital asset purchases				
g. Loans to repay				
h. Total cash outflows (e+f+g)				
i. Net cash flow (d−h)				
j. Beginning cash balance				
k. Ending cash balance (i+j)				

at a time. The equation above can be used, substituting the best predicted values for all variables except the breakeven variable, which can be represented by some symbol, and setting the value for change in profit equal to zero. Then the equation can be solved algebraically for the value of the unknown variable. The farm manager can then form an opinion about whether the future value of the key variable is likely to be higher or lower than the breakeven value. An example of a key variable might involve the expected increase in average yield from adding irrigation to what is currently a nonirrigated operation.

Cash flow budgets

Sometimes the farm manager is concerned about having enough cash on hand to meet all expenses, investments, and loan payments when they come due. A special type of whole farm budget, called a cash flow budget, can be used for this sort of analysis. A cash flow budget is an estimate of all the expected cash inflows and cash outflows the farm will have during the next accounting period, often the calendar year. The cash flows are usually estimated separately for shorter time periods within the year, such as months or quarters, as well as summarized for the year as a whole.

A cash flow budget contains most of the same revenue and costs that are found in a whole farm budget, but it also includes some other sources and uses for cash. Four general categories of cash inflows are: cash income (generally from sales of farm products and other miscellaneous sources of revenue), sales of capital assets (revenue generated by selling long-term assets such as machinery, land, and buildings), new loans received (funds borrowed from outside lenders), and nonfarm revenue (infusions of cash generated from outside the business).

The categories for cash outflows are analogous to the inflow categories. Cash expenses are generally shown first. Note that cash expenses do not include depreciation nor opportunity costs, because they are not actually paid in cash. The next category is purchases of capital assets. These are assets that would normally last for more than one production cycle. The third category is repayment of loans. Both interest and principal payments are often combined in the loan payment category as both involve cash outlays. The last category is nonfarm expenditures, which can include cash withdrawals from the business, such as those used for family living expenses or other nonbusiness purposes (Table 3).

The difference between total cash inflows and total cash outflows is called net cash flow, which can be either positive or negative for each time period. Any cash funds left over from the previous accounting period are added to the expected cash inflow in the first time period to estimate the cash balance left at the end of the period. This balance is then added to the cash inflow for the next time period, and so forth, until all time periods have been budgeted.

The object of the budget is to project a positive cash balance at the end of each time period. If some periods do not project a positive cash balance, several actions can be taken. The most common one is to increase the amount of borrowing. This action may be shown in a separate section that projects loans and repayments from a line of credit that has been extended by a lender. The projection for the amount of cash to be borrowed should be large enough to show a positive cash balance at the end of the period. Many managers try to budget for a larger balance, to allow for any errors in projecting either the cash inflows or outflows.

Other revisions to the budget can include shifting sales to periods that have a cash deficit or moving cash expenditures to periods that have excess cash available. Of course, these changes must be realistic given the planned enterprises and production cycles for the budgeting period.

It is important to note that a cash flow budget does not measure expected profits for the farm. It merely tracks expected cash inflows and outflows, many of which are not considered income or expenses in the economic or accounting sense. Nevertheless, a cash flow budget is an important financial management tool, and should be shared with any lenders who will help finance the farm business.

Implementation

A successful farm manager must not only do a careful job of planning, but also must be able to acquire the proper type and scale of resources necessary to carry out the plan. Many good farm plans have failed because certain key resources were lacking. Farm businesses require a well-managed mix of financial, human, land, and physical resources to operate successfully.

Financial Resources

Most farmers start with some of their own assets, including a certain amount of cash with which to fund initial operating costs and investments. This is called equity capital. Farmers who have been in business for many years, or who are fortunate enough to inherit an ongoing farming operation, may operate entirely with equity capital. As long as a lack of capital does not limit the size or efficiency of the farm business, 100% of the return earned on capital goes back into the farmer's pocket.

Many farmers, probably a majority, depend on outside sources for loans, or debt capital. The wise use of debt capital in large measure determines whether farm businesses grow and prosper or eventually fail.

The most common source of debt capital for farmers is commercial banks. Banks are in business to lend money, for a variety of purposes. In particular, banks located in rural areas depend on farm loans for much of their business, and their loan officers become skilled at evaluating loan applications and monitoring agricultural credit lines. Banks particularly like to lend funds for purchasing crop inputs and feeder livestock because these funds are repaid quickly. Lenders expect the farmer to be able to repay the loans from the sale of the crops or livestock that were financed. Hence, these types of loans are called 'self-liquidating,' and carry a low level of risk for the lender.

Commercial banks also make loans for capital assets such as machinery, breeding livestock, buildings, and land. The assets purchased with the loan funds serve as collateral, although most lenders will ask for additional assets to be pledged, as well. Interest rates may be fixed for a few years, but often are adjusted later to match the interest rates that the bank must pay to obtain funds to lend.

Sometimes farm loans can be obtained from financing institutions created specially to assist agriculture. In the United States the Farm Credit System (FCS) functions as a cooperative or credit union for farmers. The FCS sells bonds on national money markets and passes the loan funds to the farmer members. The FCS is organized into several regional banks within the United States, each of which has local offices that accept loan applications and manage outstanding loans. Profits earned are passed back to the farmer members. The FCS and similar institutions lend exclusively to farmers and ranchers and thus have developed high degrees of expertise in analyzing agricultural credits. They generally provide loans for both short-term operating needs and longer-term asset purchases.

Not all farmers have the experience or equity necessary to qualify for credit from a private bank or credit institution. In some cases the federal government steps in as a temporary lender, to finance beginning or high-risk operators until they can obtain credit from commercial sources. Often the government lenders offer lower interest rates and longer terms, to improve the borrowers' repayment capacity. Some public sector lenders may make loans targeted at growers of specific commodities or certain groups that have been underserved in the past.

Another source of credit for farmers can be the businesses that supply them with seed, fertilizer, or machinery. These businesses extend credit as a way of encouraging farmers to purchase their products, which of course is a condition for receiving a loan.

Some farmers find that they can stretch their limited equity capital by leasing certain assets rather than owning them. Land is the most commonly leased asset, but lease agreements for machinery, buildings, and breeding livestock are also available. Leases may be offered by independent companies affiliated with equipment manufacturers or representing large investment firms.

Farmers who utilize credit must carefully manage how much they borrow and when they plan to repay it. Cash flow budgets, both short term and long term, are useful for testing the feasibility of credit use. Farm businesses that depend heavily on credit are said to be highly leveraged. Often they use credit to acquire additional resources, so that the business can operate at a more efficient level and fully support the operator and family members. In times of high prices and wide profit margins, being highly leveraged can help businesses increase net worth rapidly. By the same token, when prices are low or production is below average loan payments must still be made. Net worth may shrink as operating capital is diminished or some assets are liquidated. Eventually the farm may not be able to continue as a viable business. The prudent manager will employ one or more risk-control strategies to prevent such a situation from happening.

Human Resources

Historically, agriculture has been a very labor-intensive industry. Moreover, farming has often involved very hard physical labor under extreme climatic conditions. Fortunately, innovations in agricultural technology have reduced the physical effort needed to produce livestock and crops. At the same time, each farmer or farm worker is able to produce many more units, leading to higher net incomes. Ever more sophisticated machinery and equipment require more training and higher skill levels.

Unlike many industries, agriculture depends to a large extent on the labor supplied by the same individuals who own and manage farms. In the United States, only about a third of the total labor force in agriculture consists of paid employees. Even farms that do hire labor may have only one or two full-time employees. At the other extreme, there are farms that employ hundreds of workers annually. Labor management issues on these large farms are vastly different than those of smaller 'family' size farms.

Farm managers must deal with the seasonality of labor needs. Crop farms may need large amounts of labor during planting and harvesting seasons, but their needs are much lower during other months. Livestock operations may have high labor needs when offspring are being born, but not during other seasons. Farm managers must determine what mix of full-time and seasonal or part-time labor will assure that critical tasks are performed on time without committing to higher than necessary expenditures on wages and salaries.

Setting compensation levels for farm employees can be difficult, because each worker may have a unique job description and set of skills. Besides cash wages, farm employees often receive fringe benefit packages that include health

insurance, clothing, meals, and even housing. Some employers offer bonus schemes that reward workers with extra income or other benefits if performance levels meet or exceed certain standards. To serve as an effective incentive for higher job performance, the bonus must depend on factors that are at least partly under the employee's control.

Farm managers also need to be aware of laws and regulations that apply to farm workers. Such laws may address minimum wages, withholding for taxes or unemployment funds, safety considerations, immigration status, and work restrictions based on age.

Human resources also include consultants and hired experts. Some duties of a farmer can be outsourced more efficiently than they can be done in-house. Preparation of tax reports, farm accounting, crop scouting, and livestock health procedures are examples of services that are often contracted to outside consultants and practitioners.

Land Resources

Ever since humankind moved from hunting and gathering to growing crops and domesticating livestock, access to land has been critical. Many battles have been waged over rights to land necessary for feeding a growing population. The specific land tenure systems present in a country or region often determine the distribution of income and opportunities among its population.

Although some societies have operated with communal holding of agricultural land, most countries with highly developed agriculture allow land to be held as private property. This means that farmers must either own land themselves or enter into some type of rental agreement with the owner. Many farms involve a mix of owned and rented land.

Purchasing land usually requires a substantial capital outlay. Because land does not depreciate, assuming it is cultivated properly, it has a higher purchase price relative to its income-generating capacity than other agricultural assets. Purchases of farmland are often possible only with the use of borrowed funds. Lenders typically will not lend the entire purchase price for land, so the farmer must use equity capital for part of the purchase, called a down payment. Repayment terms for farm real estate loans are usually fairly long, as much as 20–30 years or more. For an established farmer, purchasing additional land is often made more difficult by the fact that land is immobile, that is, it cannot be moved to the farmer's current location. Therefore, farmers are often willing to pay a premium for a tract of land that adjoins or is very close to their present base of operations.

Agricultural land values have been the subject of much study and scrutiny. The value of a tract of farmland can be estimated using a standard formula for assets that provide an infinite stream of income, called a 'perpetuity.' First, the annual net income that can be earned from the land must be estimated by using the budgeting procedures discussed previously. This value is then divided by the discount rate, which is the expected real rate of return on similar assets. The discount rate can be estimated by subtracting the expected rate of inflation from the farm's cost of capital, including both debt capital and equity capital. The result is the amount that can be paid for the land that will allow the buyer to earn a rate of return equal to the discount rate. If the farmland is located near urban or recreational areas, its value may be higher than its expected returns in farming would indicate, due to its potential for other uses.

Farm managers who are not able to own a sufficient area of farmland often turn to rental arrangements. Renting or leasing land does not guarantee that the farmer will have use of it indefinitely, but it usually requires less of a capital commitment than ownership does. In many parts of the United States as much as 60–70% of the farmland is rented rather than owned by the operator.

The most straightforward type of rental agreement is called fixed cash rent. The farmer agrees to pay the landowner a set fee for the use of the land, and must supply all other resources such as labor, machinery, and crop inputs. The rent may be payable in advance, after the crop is harvested, or in several installments. The renter takes all the risk for uncertain prices, yields, and production costs. In some cases the tenant and the landowner may agree to a flexible cash rent arrangement, under which the actual rent to be paid varies according to the actual yields and/or prices attained. In these cases the landowner not only shares part of the risk, but also receives a higher return when results are better than expected.

Share lease arrangements are also common, and in some areas outnumber cash leases. Under a share lease the tenant and the landowner divide production in an agreed-upon proportion, and no cash payment is made. The size of the landowner's share generally reflects the productivity of the land, reaching as much as 50% in some regions. In addition, the owner and the tenant usually share the costs for inputs that are yield increasing in the same proportion as the crop is divided. This ensures that the optimal level of input use is maintained, that is, the level at which marginal cost and marginal revenue are equal is the same for both parties. Labor and machinery are typically contributed completely by the tenant, although many variations of share leases exist.

A key feature of a share lease is that the risks of low prices, low yields, or high input costs are shared between the tenant and the landowner in the same proportion as the crop and input costs are shared. Moreover, the tenant's capital requirement at the beginning of the crop cycle is reduced considerably, because no advance rent is paid and the landowner finances a portion of the crop inputs.

Share leases can also be used for livestock farming operations. Usually the tenant and the owner both own a share of the livestock, and pay for a like percentage of feed and other cash costs.

Other Capital Assets

Most farming operations also require machinery, storage buildings, livestock production buildings, processing and handling equipment for feed, water, and manure, and other types of capital assets. These assets can be acquired with either equity capital or debt capital, or some other combination. As noted earlier, these assets can also be leased from financial companies or farm landlords. In many cases they are designed for very specialized uses, so the farm manager must be committed to carrying out the enterprises for which they are

intended. They generally need to be used to their full capacity in order to keep ownership costs per unit of output at a minimum.

Managing Risk

No matter how carefully a farm manager develops budget projections of costs and returns, they will never be a perfect prediction. Random events such as weather, pests, accidents, disease, product prices, and input costs cannot be forecast with complete accuracy. This does not mean that the manager should not carry out any risky strategies; rather, certain measures should be taken to limit the damage should unfavorable outcomes occur. Several general types of risk-management tools are available.

Reducing the range of possible outcomes means that the chances of a very bad outcome are reduced, but the possibility of a very good outcome may also be reduced. Strategies that reduce the range of possible outcomes include using share leases, fixing selling prices in advance, spreading product sales over time, diversifying the mix of enterprises, and keeping financial leverage to a low level.

Insurance strategies allow the farm manager to pay a small fee on a regular basis in exchange for receiving a payment to offset damages suffered when a loss occurs. Insurance policies are available for property damage, liability suits, theft, injury, and death. Crop insurance policies that provide coverage for yield losses and unexpected declines in selling prices are becoming increasing popular. In the United States, commodity options are available which fix a minimum selling price for a product, for a fee.

A third general strategy is to maintain resources in reserve so that an adverse result is less likely to affect the survival of the farm business. Financial reserves and lines of credit are especially useful, but keeping a reserve feed supply for livestock or having someone who can provide backup labor and management in an emergency also falls within this category.

Control and Evaluation

The third phase of farm management is control and evaluation. In this phase the manager collects data, both physical and financial, and uses it to determine if progress is being made toward the goals that have been set for the farm business. Based on this information, needed changes in strategies can be identified and new budgets can be created for the next planning cycle.

Information Management Systems

Most businesses have accounting systems for tracking income and expenses. In many countries farmers are required to submit reports for income tax purposes, so those requirements may define the minimum amount of information needed. However, for effective management purposes additional information is needed. The total process for collecting, summarizing, and interpreting data about what takes place on the farm is called an information management system. The exact composition of a system will depend on the type of products that the farm produces, its legal and business organization, and the particular decisions that the manager faces.

The information management system should be no more complicated than necessary to meet the needs of the manager. Information is needed for two general purposes: internal reports that help the manager make more informed decisions about enterprise choice, technology to follow, marketing plans and financing strategies; and external reports, which may be required by lenders who are providing capital to the business, partners or landowners who share or rent resources, and the government to meet taxation and other obligations.

Several decisions must be made before an information management system can be put into practice. One such decision is the accounting period to use. The most common choice is 1 year, often the calendar year. However, other periods can be used if they better fit the particular needs of the business. Farms in the southern hemisphere may choose to start their accounting period late in the year, when annual crops are likely to be planted, and end it in the first half of the following year, after harvest is completed.

Cash accounting systems record income when it is received and expenses when they are paid. Accrual systems, however, recognize income when crops or livestock are produced, or at least when they are ready to be sold, even if they may be stored or held until a later time. Accrual accounting also records expenses when they are incurred, even if they are not paid at that time. This difference is particularly critical at the end of the accounting year, when mature crops and animals may still remain on the farm, and some expenses either have not been paid yet, or have been paid in advance. The fundamental purpose of accrual accounting is to recognize the value of farm products as income in the year they are produced, and to recognize all the costs of producing them in the same year.

Each time income is received or recognized, or an expense is paid or recognized, a transaction is entered into the accounting system. The details of each transaction usually include the monetary value, the date it occurred, the entity or person from whom the income was received or to whom the expense was paid, the purpose, the quantity sold or purchased, and the sale or purchase price. Transactions can be entered into a hand record book or a computerized system – the principles are the same.

Periodically transactions are posted to accounts. In a single-entry accounting system, transactions affect only income or expense accounts. In a double-entry system, adjustments are also made to asset and liability accounts. More details about these accounts are discussed later. The number and nomenclature for the various accounts depend on the type of commodities being produced, the specific inputs being used, and the degree of detail desired in the farm's financial statements. When an accounting system is implemented, a chart of accounts is defined, which shows the title for each income, expense, asset, or liability account that the farm wishes to use.

Financial Statements

Once an accounting year is completed and all the relevant transactions have been entered and posted, several summaries or financial statements can be created. Four such statements

have been recommended by the Farm Financial Standards Council, a group composed of accountants, lenders, and agricultural educators that has developed guidelines for financial accounting for farmers and ranchers. Their objective is to increase the degree of consistency in the terminology used, the formulas for calculating certain key ratios, and the procedure for handing certain accounting questions related to agriculture.

The net worth statement

The net worth statement, also called the balance sheet, is a summary of everything the farm business owns (assets) and owes (liabilities) as of a certain date. Traditionally, a net worth statement is developed at the end of the accounting year and is called the ending or closing statement. The same statement serves as the beginning statement for the next accounting year. A net worth statement can be created at any point in time, however. Because it is the primary document that lenders use to evaluate a farm's application for a loan, a current net worth statement may be requested for each new credit application. In a double-entry accounting system, the asset and liability accounts will always be up to date. However, if a single-entry system is being used, the farm manager will have to collect current information about each asset and liability on the date the statement is constructed.

Both the assets and the liabilities on the net worth statement are subdivided into several categories, according to how quickly they could be turned into cash (assets) or repaid (liabilities). Assets that normally are sold or used within the next 12 months are classified as current assets, as are other assets that can be easily converted to cash, such as stocks, bonds, or other financial assets. Assets that will normally be present on the farm beyond the next 12 months can be classified as intermediate (1–10 years) or long term (more than 10 years). In practice, intermediate assets usually consist of machinery, equipment, and breeding livestock, and long-term assets consist of land, improvements to the land, and buildings. In some accounting systems intermediate and long-term assets are combined under the heading of fixed or noncurrent assets. Liabilities are classified in a manner similar to assets, based on how quickly they are expected to be repaid.

Although the value of debts and other obligations are generally well known, assigning values to assets may require some judgment. In general, current assets are valued at the price for which they could be sold on the date of the statement, or their original cost. Depreciable assets, such as machinery, are generally valued at their original cost minus any depreciation expenses taken since that time. If the depreciation accurately reflects the loss in value of the item, the price that could be received for selling the asset should closely mirror the depreciated value. Owned land can be difficult to valuate. If it has been owned for several years, the purchase price may no longer reflect the market value, but market value for land in rural areas can be difficult to determine accurately.

The balance sheet can be constructed using a 'cost' approach, which generally values assets by using the original purchase price or the depreciated value, or using a 'market' approach under which assets are valued at their expected market price, if sold. The cost approach is generally the more conservative of the two methods, but market values are more useful for comparing the farm's financial condition with that of other farms.

The net income statement

The second-most common financial statement used in farm management is the profit and loss statement, also called the net income statement. It summarizes the income, expenses, and profit (or net income) generated by the farm during the past accounting cycle. Profit and loss statements can be generated using either cash or accrual accounting methods. Small farms often use a hybrid approach. Cash income and expenses are recorded throughout the year. Then, at the conclusion of the year, the value of all unsold production is added to the cash income and the value of all unsold production at the beginning of the year is subtracted. Thus, an increase in the value of current inventories results in a higher estimate of income, and vice versa. This ensures that the value of crops and livestock produced on the farm is counted in the year it is produced.

Expenses can also be adjusted at the end of the year, by adding to the total cash expenses any change over the accounting period in accounts payable and also by subtracting any change over the accounting period to expenses paid in advance. The result is an estimate of accrual net income, a more accurate estimate of the farm's net earnings than cash net income.

The farm manager must be careful not to count the receipt of loan funds or the repayment of loan principal as income or expense. These transactions simply represent borrowing and repaying capital provided by a lender and not earned income nor costs of production. Any interest paid on such loans is an expense, however.

The statement of cash flows

Loans received and repaid are included in the third statement, the statement of cash flows. Likewise, cash income and expenses as well as sales and purchases of capital assets are included in this statement. The statement of cash flows is very similar to a cash flow budget, except it summarizes past revenues and expenditures instead of projecting future ones. Nonfarm income transferred into the farm's finances, or funds withdrawn for nonfarm purposes are also reported in this statement. The sum of all cash inflows to the business, plus the cash that was in the farm bank account at the beginning of the year, should equal the sum of all the cash outflows, including the balance in the farm account at the end of the year. This is a good way of checking to see if all the cash received and used during the year has been accurately recorded.

The statement of owner equity

One more financial statement completes the recommended set. The statement of owner equity shows how the net worth of the farm changed from the beginning of the accounting year to the end. Net worth will change by the value of net farm income (accrual based) plus any outside funds invested in the farm (including gifts or inheritances) minus any funds withdrawn from the business. Net worth may also be changed by valuing some intermediate or long-term assets according to their market value, that is, the value they could reasonably be sold for, rather than their cost or book value, which is their

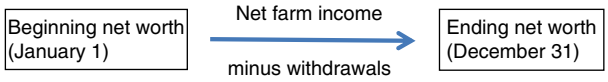

Figure 1 Relation between net worth and net farm income.

original cost minus any depreciation expense taken to date. Some farm accounting systems show net worth based on both cost and market values. Cost values more closely adhere to traditional accounting rules, but market values give a better picture of the value of the farm's assets for the purpose of collateralizing loans (Figure 1).

Farm Business Analysis

An accurate set of financial statements can provide valuable information for calculating certain ratios and indicators of the financial health of the farm. Three general areas of financial management are important: solvency, profitability, and liquidity.

Liquidity

Liquidity is the ability of a farm to meet its cash flow obligations on time. One common measure of liquidity is working capital, calculated by subtracting the current liabilities shown on the net worth statement from the current assets shown on the same statement. This is an estimate of how much cash would be left over if all the assets that will be sold or used up in the next year were used to pay all the liabilities that are due within the next year. A similar measure is the ratio of current assets to current liabilities, usually called the current ratio. Of course, a cash flow budget, as described in the Section Cash flow budgets, does a much more detailed job of analyzing the liquidity of a farm.

Solvency

Solvency refers to the relative values of a farm's assets and liabilities. Solvency is usually measured using current market values for capital assets. This allows lenders and managers to compare farms against each other, and to industry standards. The most common measure of solvency is simply the farm's current net worth. It represents the value of the farm's assets that would be left if all liabilities were paid to zero. Because net worth is closely tied the size of the farm business, the ratio of total liabilities to total assets is also used to evaluate solvency, allowing farms of different sizes to be directly compared.

Profitability

Profitability is the degree to which the value of a farm's production exceeds the cost of the resources used to produce it. An absolute measure of profitability is net farm income. If the opportunity costs for the farmer's own labor and capital are subtracted, the remainder is profit and return to management. A positive profit means that the farm has produced crops and livestock that have a greater value than the seed, fertilizer, fuel, labor, feed, and other inputs that were used up in their production. Profits are also highly correlated with farm size. To compare the profitability of farms of different sizes, several ratios are used. The asset turnover ratio is equal to the gross revenue for the entire farm divided by the value of its total assets. It reflects the efficiency with which land, machinery, breeding livestock, and other resources are turned into food, fuel, and fiber. Another common ratio is the rate of return on assets (ROA), which is a measure of how much the total assets earned, on a percentage basis. It can be compared to what the farmer could have earned if the total value of the assets had been invested elsewhere.

To be useful, all farm business analysis measures must be compared to benchmark values. Past records from the same farm calculated in the same way can show if the farm is progressing or going downhill in each area. Comparing to projected values from enterprise or whole farm budgets developed at the beginning of the year will show if reality exceeded expectations or otherwise. Perhaps, the most useful benchmarks are comparable ratios for the same year from similar types of farms located in the same area. Farm managers can quickly determine in which areas their business exceeded other farms, and which areas need improvement.

Enterprise Accounting

Just because a farming operation is profitable overall does not mean that each part of the farm is earning a profit. Only by matching income and expenses to individual enterprises can the weak and strong areas of the farm be identified. Enterprises can be defined in the same manner as for enterprise budgets. Generally, each major crop or livestock species is evaluated separately, although livestock enterprises can be further divided by phase of development. In managerial accounting, businesses are divided into profit centers, and each one is analyzed to see how well it contributes to the overall profits of the company. Farm enterprises are analogous to profit centers.

Some enterprises generate products that may be used as inputs by other enterprises. The most common example is grain or forage that is grown on the farm and fed to livestock on the same farm. To fairly assign income and expenses to each enterprise, the market value of the fed crops should be attributed to the crop enterprises as income and assigned as costs to the livestock enterprises that consume them. This adjustment is called an internal transaction. The income to one enterprise is exactly offset by the cost to the other enterprise, so there is no effect on total farm net income or profit. Other examples of internal transactions include assigning the nutrient value of animal manure used as fertilizer as income to the livestock and an expense to the crops, and assigning the value of weaned calves as income to the beef cow herd and an expense to the feedlot enterprise.

The time period used for enterprise analysis often differs from the whole farm accounting year. Enterprises are more logically summarized from the beginning to the end of each production cycle. A winter wheat crop may be sown in one accounting year, harvested in the next year, and sold in the third year. An accurate evaluation of that crop would include transactions occurring in three different accounting years. However, certain vegetable crops or a livestock enterprise such as swine farrowing may have multiple production periods within the same year.

To assign revenue and costs to the proper enterprise the farmer should enter them in separate sections or columns of the record book when transactions are posted. In a

computerized accounting system different numerical codes are assigned to each transaction, with each code representing a different enterprise.

Summary

Farm management is both a science and an art. It requires vision about the future of agriculture, but it also requires skill at collecting and interpreting data, searching for new resources, and dealing with uncertain outcomes. It requires much patience, but can also yield great rewards.

Glossary

Backslopping Practice of retaining small quantities of fermented product from the successful manufacture of a fermented product in the previous batch and using it as the inoculum or starter in the next batch.
Condiment An edible substance such as sauce that can be added to food to impart a particular flavor, or to improve its flavor, or to complement the dish.
Heterofermentative Producing a fermentation resulting in a number of end products.
Homofermentative Producing a fermentation resulting wholly in a single end product.
Probiotics The World Health Organization defines probiotics as "live microorganisms, which when administered in adequate amounts, confer a health benefit on the host."
Spontaneous fermentation Also called natural fermentation is a method of fermentation that does not require addition of a starter culture such as yeast to start and control the fermentation of the substrate.

Introduction

Fermented foods are of great importance because they provide and preserve great amounts of nutritious and healthy foods in a wide diversity of flavors, aromas, and textures, which enrich the human diet. They are the source of alcoholic beverages, vinegar, pickled vegetables, sausages, cheeses, yoghurts, vegetable protein amino acid/peptide sauces and pastes with meat-like flavors, and leavened and sour-dough breads. Fermented foods are food substrates that are invaded or overgrown by edible microorganisms whose enzymes, particularly amylases, proteases, and lipases hydrolyze the polysaccharides, proteins, and lipids to nontoxic products with flavors, aromas, and textures pleasant and attractive to the human consumer (Steinkraus, 1997). Fermentation also ensures microbiological safety of food and may also make some foods more digestible, and in the case of cassava, fermentation reduces toxicity of the substrate. Milk, meat, cucumber, and cabbage are the main substrates used in the commercial production of fermented food. These substrates yield over 400 varieties of cheese of 20 distinct types and a very extensive range of yoghurt and fermented milk drinks, fermented sausages and salamis, pickles, and sauerkraut (Caplice and Fitzgerald, 1999).

Fermented Vegetables

Sauerkraut

Sauerkraut is a fermented product made from cabbage and has its roots in central Europe. Germans and the Alsatians prepare sauerkraut as their national dish (Sauerkraut, 2009). Sauerkraut has also been used in Germany for medicinal purposes; traditionally in many parts of southern Germany, some families would feed their children raw sauerkraut two times every week – this was believed to support and strengthen the intestines of the sick children. Sauerkraut is also traditionally produced in the Balkans using whole heads of cabbage instead of shredded cabbage. It is usually produced by spontaneous fermentation. In spontaneous sauerkraut fermentation, *Leuconostoc mesenteroides* initiate the fermentation process, followed by the growth of other lactic acid bacteria (LAB), mainly *Lactobacillus brevis*, *Pediococcus pentosaceus*, and *Lactobacillus plantarum* species, among which *L. plantarum* is responsible for the second phase of fermentation and high acidity of the produced sauerkraut. The dominant species, present in the fermentation, shift within 1 week from less acid-tolerant heterolactic to more acid-tolerant homolactic fermenting LAB species. Shredded cabbage fermentations start with 10^6 colony-forming unit (cfu) g^{-1} aerobic microorganisms, 10^6 cfu g^{-1} enterobacteriaceae, and less than 10^2 cfu g^{-1} yeasts and molds (Tamang and Kailasapathy, 2010). According to Tamang and Kailasapathy (2010), during the first 2 or 3 days of sauerkraut fermentation, less acid-tolerant LAB dominate, but after that more acid-tolerant LAB predominate. Each of these populations reaches concentrations of 10^8–10^9 cfu g^{-1}. The fermentation is complete in 2 weeks and at that time the most acid-resistant *L. plantarum* predominates. Salt concentration and fermentation temperature can also affect the growth of the naturally present microorganisms and the sensory properties of the sauerkraut (Wiander and Ryhanen, 2005). Two percentage of salt is usually added to the traditional fermentation, and to reduce salt waste.

In a study of two commercial sauerkrauts, Plengvidhya *et al.* (2007) reported that glucose and fructose were the primary fermentable sugars in the cabbage, with concentrations of 1.5% and 2.2%, respectively, and sucrose concentration was less than 0.2%. Lactic acid, acetic acid, and mannitol were produced, and on the 14th day the pH value of all the tanks increased from 3.4 to 3.7.

Kimchi

Kimchi is a group of fermented cabbage, radish, and garlic foods and is consumed on a daily basis in Korea. The flavor of kimchi is dependent on the ingredients, fermentation conditions, and LAB involved in the fermentation process (Lee *et al.*, 2005). Kimchi is stored for several months, when

lactic acid fermentation occurs (Lee and Lee, 2006). More than 100 types of vegetables can be used to prepare kimchi (Kim and Chun, 2005). Chinese cabbage, radish, and cucumber, with a seasoning mixture made of red pepper powder, garlic, ginger, and green onion, are among them (Nam *et al.*, 2009).

Kimchi is made through lactic acid fermentation of cabbage at low temperatures to ensure proper ripening and preservation. Because kimchi is representative of a typical open ecosystem, each batch of fermented food has a different composition of bacteria and this is dependent on ingredients and fermentation conditions, which can be variable.

LAB are the most important microorganisms in kimchi fermentation. Using conventional methods of isolation and phenotypic identification, the following species are found to be responsible for kimchi fermentation: *L. mesenteroides*, *Leuconostoc pseudomesenteroides*, *Leuconostoc lactis*, *L. brevis*, and *L. plantarum* (Kim and Chun, 2005). *Leuconostoc mesenteroides* was reported to predominate during the first hours of fermentation (Kim and Chun, 2005). The pH value gradually falls to 4 and then *L. plantarum* becomes predominant (Kim and Chun, 2005). To obtain a product of constant quality, a starter culture consisting of *L. mesenteroides* and *L. plantarum* strains was used, and the product was not different from conventional kimchi. *Leuconostoc citreum* HJ-P4, a strain isolated for kimchi fermentation, with high dextransucrase activity and adapted to grow at low temperature, has been proposed to be used as a starter culture to produce kimchi commercially (Yim *et al.*, 2008).

Fermented Beans and Cereals

Tempe

Tempe is a solid fermented soybean product prepared using nonsalted soybeans. Tempe has an overwhelming advantage in terms of odor over other nonsalted fermented soybeans (Tamang and Kailasapathy, 2010). It is widely consumed in Indonesia and there has been considerable interest in the West, especially in the USA, in developing tempe as an alternative source of protein. In Indonesia, 750 000 tons of soybeans per year are consumed as tempe (Ito, 2002). In the USA, Europe, and Japan, some food companies produce tempe on a large scale (2–6 tons week^{-1}).

Rhizopus oligosporus (*Rhizopus. microsporus* variety *oligosporus*), a fungus, is the major microorganism for the fermentation of tempe, though some bacteria have been isolated from natural tempe (Tamang and Kailasapathy, 2010). In addition, *Klebsiella pneumoniae*, *K. pneumoniae* subsp. *ozaenae*, *Enterobacter cloacae*, and gram-positive bacteria were isolated as vitamin B12-producing bacteria in tempe (Okada *et al.*, 1985). LAB is the second most important microorganism in traditionally made tempe in Indonesia. The key role of bacteria is to lower the pH of soybeans, to prevent pathogenic bacteria from growing dominantly, and to provide *R. oligosporus* with a suitable environment to multiply. Tempe preparation is rapid and takes only two days at most to complete. It is perishable and is consumed as a meat substitute. Among the nonsalted fermented soybeans, only tempe has been accepted worldwide (Tamang and Kailasapathy, 2010).

Tempe contains not only dietary fiber, saponins, and isoflavones of soybean origin but also superoxide dismutase, an enzyme that eliminates active oxygen. Strong thrombolytic activity (average 450 IU g^{-1} dry weight) was observed in tempe extract (Sumi and Okamoto, 2003). In laboratory-made tempe, the content of γ-aminobutyric acid, which improved blood flow to the brain and inhibited the elevation of blood pressure, increased when tempe was placed in an anaerobic environment after normal aerobic fermentation (Aoki *et al.*, 2003). It was also reported that a phytoestrogen, equol, derived from soybean isoflavone had a suppressive effect on prostate cancer (Horii, 2008).

Fermented Soybean Paste

Fermented soybean paste is indigenous to the cuisines of east and southeast Asia. Miso is a traditional Japanese food, and its consumption dates back to AD 700. Miso is a brown and salty fermented thick soybean paste. It contains vitamins, microorganisms, salts, minerals, plant proteins, carbohydrates, and fat. Miso also contains saponin-inhibiting lipids peroxide, trypsin inhibitor, isoflavon, lecithin, colin, prostaglandin E, and others. It is used on a daily basis as a flavor in soups and solid foods in Japan and some parts of Asia. In addition, miso adds a unique burst of flavor to salad dressings, vegetable dishes, baked tofu, sauces, and marinades. According to Hesseltine (1965); Shibasaki and Hesseltine (1962) there are three basic types of miso. There is kome miso, made from beans and rice; mugi miso, made from beans and barley; and mame miso (sold as hatcho miso in the UK) made from soybeans alone. For the production of kome and mugi misos, the koji is produced by soaking polished rice overnight in water, steaming it for approximately an hour, then inoculating with mould spores. Incubation is for 50 h at 35° with thorough stirring at least twice. The *Aspergillus oryzae* strains used for these fermentations should be higher in amylolytic activity. *Saccharomyces rouxii* and *Torulopsis* are the yeasts and *Pediococcus halophilus* and *Streptococcus faecalis* are the bacteria, principally involved in miso's spontaneous fermentation.

Miso is considered as a food with health-promoting benefits, such as effectiveness in relieving fatigue, regulation of the intestinal function, digestive supplement, protection against gastric ulcer, decrease of cholesterol, decrease of blood pressure, whitening ability, prevention of diseases associated with adult lifestyle habits, apoplexia cerebri, accumulation of brain metabolism, protection of aging, healing radiation damage, and prevention of cancers for biological effects (Watanabe).

Bibliographically, Korea developed and used its own traditional fermented foods 2000 years ago (Kwon *et al.*, 2011). Korean soy foods are increasingly present on the worldwide market, and because kochujang (fermented red pepper paste with soybean flour) and fermented soybean pastes (doenjang and chungkukjang; both chungkukjang and chungkookjang are used in the reports) were registered in CODEX in July, 2009, they are now internationally accepted foods (Kwon *et al.*, 2010). Most fermented soybean pastes are salty and savory and some are spicy. They are often used as condiments to flavor foods such as stir-fries, stews, and soups. Fermentation changes the physicochemical and organoleptic

properties of soy products such as color, flavor, and active components. Differences in their color, flavor, and active components are due to different production methods such as the conditions of fermentation; the addition of wheat flour, pulverized meju, rice; and the presence of different microflora such as bacteria or yeasts used in their production, as well as whether the soybeans are roasted (as in chunjang) or aged (as in tauchu) before being ground. In addition to physicochemical properties, the fermentation of these soybean products changes the bioactive components, such as isoflavonoids and peptides, in ways that may alter their physiological properties in terms of healthy health functions and efficacies.

Fermented Cereal

Cereal-fermented foods involve a lactic acid fermentation step in most cases, which can be associated with an alcoholic fermentation step depending on the process used (e.g., brewing). It is now commonly known that lactic acid fermentation contributes to human welfare through the preservation of foods, the development of organoleptic characteristics and nutritional improvement of foods, and the health-promoting effects of lactic acid bacteria (probiotics) (Nout and Motarjemi, 1997; Charalampopoulos *et al.*, 2002; Kohajdova and Karovicova, 2007).

Lactic acid cereal-fermented foods and beverages are made from a great variety of cereals involving different processing methods. Maize, millet, and sorghum grains in Africa are used to produce such lactic acid-fermented foods like *ogi* (Benin, Nigeria), *togwa* (Tanzania), *bushera* (Uganda), *ben-saalga/koko* (Burkina Faso, Ghana), *gowe* (Benin), *mawe* (Benin), *kenkey* (Ghana), *hussuwa* (Sudan), *mahewu* (Zimbabwe), *poto poto* (People's Republic of Congo). In many African countries, the same cereals can be germinated to produce malt for their use in brewing of cereal slurries to make traditional beers of thick consistency, called under different vernacular names such as *dolo* in Burkina Faso; *bili bili* in Tchad; *burukutu* in Nigeria; *pito* in Ghana; and *kaffir*, a Bantu beer, in South Africa. In Mexico and Guatemala, maize is used to produce *pozol* whereas rice is used to produce *selroti*, *bhaati jaanr*, *idli*, *dosa* in India, and *burong isda* in the Philippines. In the Himalayas, various cereals like finger millet, wheat, maize, and barley are used to produce different kinds of fermented beverages like *kodo ko jaanr* and *gahun to jaanr*, and if we consider the particular case of the Balkan Peninsula, rye, wheat, millet, maize, rice, barley, and oat are used alone or in mixtures to produce *boza*.

Fermented Milk

Yogurt

Yogurt is the most popular and successful fermented milk product all over the world and is manufactured by scientifically sound technologies in modern dairy factories. It is similar to some traditionally made yogurt manufactured thousands of years ago. Yogurt is a widely consumed highly nutritious fermented milk, defined by the Codex Alimentarius (FAO/WHO, 2003) as a coagulated milk product resulting from the fermentation of milk by *Streptococcus. thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus* (formerly *Lactobacillus bulgaricus*). Among the factors contributing to the great success of this fermented milk product, the image of a natural product, attractive organoleptic characteristics (fresh, acidulated taste, and pleasant flavor), nutritional value, prophylactic and therapeutic properties, and moderate cost (due to the high productivity of the production lines) can all be mentioned (Tamime and Robinson, 2007). Varieties of yogurt available include plain (set), fruit-flavored, whipped, drinking type (stirred), smoked, dried, strained, and frozen (Tamime and Robinson, 2007).

The desirable typical flavor of yogurt comes from a mixture of lactic acid, carbonyl compounds (acetaldehyde, acetone, diacetyl, acetoin), nonvolatile acids (pyruvic, oxalic, succinic), volatile acids (formic, acetic, propionic), and a large series of degradation products from the catabolism of proteins, fats, and lactose. In general, yogurt has less lactose and more lactic acid, galactose, peptides, free amino acids, and free fatty acid than milk (Tamime and Robinson, 2007). Apart from its high nutritional value, yogurt has a lot of health benefits. Beneficial health effects are presumed to depend on the ability of *S. thermophilus* and *L. delbrueckii* to reach the gastrointestinal tract alive, where they persist and/or multiply. However, there have been conflicting studies concerning the culture recovery of *L. delbrueckii* subsp. *bulgaricus* and *S. thermophilus* from fecal samples after yogurt ingest; whereas some authors reported recovery of both bacterial types (Mater *et al.*, 2005; Elli *et al.*, 2006), some others have failed to do so (del Campo *et al.*, 2005).

Cheese

Cheese in Europe has traditionally been considered the preferred outlet for milk after local fresh milk requirements have been met. The EU cheese market is the largest in the world. Cheese has therefore provided much better export opportunities than any other dairy product as the willingness to pay for high quality European cheese has always been high.

Most cheeses in Europe are produced on a commercial scale using the appropriate LAB starter culture. Thermophilic strains are generally used in cheeses with a high cooking temperature such as Swiss and Italian types (Caplice and Fitzgerald, 1999). Secondary microflora are added in some processes to improve texture (e.g., the production of CO_2 by Propionibacterium in Swiss cheese) and flavor (e.g., by the production of diacetyl). Moulds, yeasts and bacteria other than lactic acid bacteria are used as secondary microflora in some varieties of cheese.

Fermented Fish

There are many varieties of fermented fish products available at present. Fermented fish products include liquid products such as fish sauce also known as *nampla* in Thailand, *kecap ikan* or *bakasang* in Indonesia, *patis* in the Philippines, *nouc-mam* in Vietnam, oyster sauce, *hoi-sin* sauce, and paste products such as fish and shrimp pastes also known as *belacan* or *terasi* in Indonesia and Malaysia, and dry and semidry fermented fish.

Lightly salted fermented fish are mostly produced in southeast Asia (Adams *et al.*, 1985; Ishige, 1993; Phithakpol *et al.*, 1995) and their traditional culinary use is widespread throughout the region. Plaa-som is a popular Thai fermented fish produced according to family or local geographical preferences, especially in the central, northeastern, and northern parts of Thailand (Saithong *et al.*, 2010). According to Saithong *et al.* (2010), differences exist in production methods of plaa-som and the use and proportions of raw materials, which typically consist of freshwater fish, salt, a carbohydrate source (cooked or raw rice), and garlic. All ingredients are mixed and left to ferment at ambient temperature (25–30 °C) for 3–5 days in either a covered-lid cooking pot, a wrapped package using a thin plastic sheet, or a plastic bag. The traditional production of plaa-som is based on spontaneous fermentation due to the development of the microflora naturally present in the raw materials. The quality of the end-product is dependent on the microbial load and on the spectrum of the raw materials. At present, the production of plaa-som on a large scale has become an important branch of the fermented food industry in Thailand and efforts are being made to develop effective starter cultures for use in plaa-som production to help improve the fermentation process.

Fermented fish products are also found in other parts of the world including the Scandinavian region in Europe, Africa, and the Middle East. In Scandinavia, whole herring or trout eviscerated but retaining the roe, are immersed in low concentration brine for 30–40 h, during which vigorous fermentation takes place (Tamang and Kailasapathy, 2010). These products are known as surstromming for herring and rakorret for trout (Beddows, 1985). Surstromming is regarded as a great delicacy in Sweden. In France and Spain, fermented anchovy products are common. Anchovy is used in the preparation of *nouc-mam*, *nampla*, and *jeotkuk*. The fish is beheaded and gutted (or ungutted in Spain), then layered with salt in barrels, weighed down to extract the pickle as it forms, and fermented for 6–7 months. The fermented fish retains its form. Lactic acid bacteria are found as the dominant microorganisms in many fermented fish products (Orillo and Pedersson, 1968; Saisithi *et al.*, 1986; Olympia *et al.*, 1992; Østergaard *et al.*, 1998). A combination of low pH and organic acids (especially lactic acid) is the main preservation factor in fermented fish products. Generally, pH should be below 5–4.5 in order to inhibit pathogenic and spoilage bacteria (Owens and Mendoza, 1985). The enzymes for the fermentation process come partly from the digestive system of the fish and partly from the bacteria that are naturally present in the fish and salt. The accumulation of lactic acid prevents the decomposition of protein into its basic components such as CO_2 and H_2O (Olympia, 1992).

Fermented Meat

Fermented meats originated independently in a number of regions around the world, although European-style products now predominate in terms of their scale of production and the degree to which they have been subjected to scientific scrutiny (Tamang and Kailasapathy, 2010). These sausages are produced by fermenting with LAB a mixture of minced meat mixed with fat, salt, curing agents (nitrate/nitrite), sugar, and spices. Fermentation temperatures are usually less than 22 °C for dry and mould-ripened sausages and 22–26 °C for semidry varieties (Lucke, 1998). Traditional sausages are usually manufactured in small-scale plants following spontaneous fermentation. Sausages produced with and without added starter culture have final pH of 4.6–5.0 and 4.0–4.5, respectively. European fermented sausages formulated with nitrite are produced with added starter culture, generally consisting of lactic acid bacteria (*lactobacilli* and *pediococci*) and catalase-positive cocci (*S. carnosus*, *Micrococcus varians*). The use of starter cultures ensures a good quality, standardized, and safe product.

The production and consumption of fermented meats expanded throughout Europe in the middle ages and were adapted to climatic conditions (e.g., smoked in northern Europe and dried in Mediterranean countries). A wide variety of fermented sausages is being produced in Europe and the variations depend on raw materials, microbial populations, and processing conditions. For example, northern-type sausages, which contain beef and pork as raw meats, are ripened for short periods (up to 3 weeks), and are usually subjected to smoking. In these sausages, shelf life is mainly due to acid pH and smoking rather than drying. However, Mediterranean sausages mostly use only pork. These sausages are ripened for longer periods (several weeks or even months), and are not typically smoked. Undry and semidry sausages are fermented to reach low pH values, and are usually smoked and cooked before consumption. Shelf life and sausage safety are mostly determined by pH drop and reduced water activity, as a consequence of fermentation and drying, respectively. The product may be considered stable at room temperature when $pH < 5.0$, and the moisture:protein ratio is below 3.1:1 (Sebranek, 2004). Moisture:protein ratios are defined for the different dry and semidry fermented sausages in the USA, whereas water activity values are preferred in Europe.

Typical fermented products were initially based on the development and growth of desirable indigenous flora, sometimes reinforced with backslopping, which is the addition of a previously ripened fermented sausage with adequate sensory properties. However, this practice usually yielded a high heterogeneity in product quality. The use of microbial starters, as a way to standardize processing as well as quality and safety, is relatively new. At present, most fermented sausages are produced with a combination of lactic acid bacteria to achieve adequate acidulation, and two or more cultures to develop flavor and facilitate other reactions such as nitrate reduction. The most important microorganisms used as starters belong to one of the following groups: lactic acid bacteria, *Micrococacceae*, yeasts, and molds (Leistner, 1992).

One of the few studies reporting the effects of the consumption of probiotic meat products on human health was carried out by Jahreis *et al.* (2002). These authors evaluated the effect of daily consumption of 50 g of probiotic salami containing *Lactobacillus paracasei* LTH 2579 on the immunity system and blood triglycerides and cholesterol levels of healthy volunteers for a few-weeks period, and obtained moderately satisfactory results.

Fermented Alcohols

Rice Wine

Rice wine is a generic name referring to alcoholic beverages made from cereals, mainly rice, in east Asia. The beverage is known as 'rice wine' in the West because its alcohol content is approximates that of a wine. Rice wine is called sake in Japan, cheongju in Korea, and shaosingjiu in China. Sake is the national and traditional drink of Japan and is one of the most popular traditional nondistilled alcoholic drinks in the world. Most Japanese elderly people, 61% of aged men and 18% women, prefer *sake* and beer according to a questionnaire survey (Jin *et al.*, 2005). It is prepared from rice using *koji* and is a clear, pale yellow liquid containing 15–20% alcohol (Tamang and Kailasapathy, 2010). Unique strains of *Saccharomyces cerevisiae* have evolved to conduct these fermentations, generating products with high ethanol content (12–20%), attractive flavor, aroma, and odor (Kodama, 1993). The first organisms that develop in the mash under traditional fermentation conditions are nitrate-reducing bacteria such as *Pseudomonas*, *Achromobacter*, *Flavobacterium*, or *Micrococcus* spp. (Murakami, 1972). These are followed by *L. mesenteroides* var *sake* and *Lactobacillus sake*, and yeasts (Kodama and Yoshizawa, 1977). The presence of lactic acid bacteria in controlled amounts is essential for satisfactory sake fermentation because the pH of the basic mash is too high for good yeast growth or a satisfactory flavor in the finished product (Wood, 1977). The highly refined *sake* brewed by the most skillful brewers using very highly polished rice at low temperatures of 9–11 °C for 25–30 days is known as *gonjoshu* (Kodama and Yoshizawa, 1977). Most LAB that spoil *sake* are homofermentative rods and are more tolerant to ethanol and acid than nonspoilers (Inoue *et al.*, 1992). *Saccharomyces cerevisiae* strains with disrupted ubiquitin-related genes produced more ethanol than the parental strain during *sake* brewing (Wu *et al.*, 2009). Several researchers have reported on improved strains for *sake* production on an industrial scale (Hirooka *et al.*, 2005; Kotaka *et al.*, 2008; Hirasawa *et al.*, 2009).

Wine

Wine is defined as the alcoholic fermentation of grape juice or other fruits without distillation. Red wine is produced from red grapes and other dark-colored grapes. White wine is made by fermenting mashed white grapes or from dark-colored grapes with the skin, pulp, and seeds removed. Red wines and white wines have markedly different flavors, and individual wines within the white or red classification may have noticeably different tastes as well (Robinson, 1994). Consumption of red wine is common in the traditional Mediterranean diet (Trichopoulou *et al.*, 2003). Traditional winemaking has been illustrated by Walker (1998). Grapes are collected from the vineyard, destemmed, crushed, pressed, and macerated, and fermented by naturally present yeasts or by adding starters. After the desired fermentation, the mass is filtered to remove sediments and is stored in wooden casks for maturation for several months, and then bottled, matured, stabilized, and filtered into clear red or white wines (depending on the color of grapes).

Until 75–100 years ago, most wines were produced by spontaneous or natural alcoholic fermentation of grape juice by indigenous yeast flora (Pretorius, 2000). Muller-Thurgau in 1890 introduced the concept of inoculating wine fermentations with pure yeast cultures. As a result, the quality and quantity of wine production have improved (Pretorius, 2000). The source of yeasts is from the surface of the grape berry; the surface of winery equipment that come in contact with the juice during crushing, pressing, pumping, and fermentation; and air (Raspor *et al.*, 2006). Various strains of *S. cerevisiae* and *Saccharomyces bayanus* act as the principal yeasts in the fermentation of wine. At present, many wine makers purchase commercial dried preparation of these yeasts for inoculation into grape juice and for initiation of the alcoholic fermentation (Fleet, 1998). Wine fermentation is initiated the by growth of various species of non-*Saccharomyces* yeasts (e.g., *Hanseniaspora uvarum*, *Kloeckera apiculata*, *Candida stellata*, *Candida colliculosa*, *Metschnikowia pulcherrima*, *Kluyveromyces thermotolerans*) as well as *Saccharomyces* yeasts, which are generally limited to the first 2–4 days of fermentation, after which they die (Fleet, 1993; Moreira *et al.*, 2005). They achieve maximum populations of 10^6–10^7 cfu ml^{-1} before death, thereby influencing the metabolic behavior of the fermentation and the products released into the wine, and their death is attributed to an inability to tolerate the increasing concentrations of ethanol, which is largely produced by the *Saccharomyces* species (Tamang and Kailasapathy, 2010). After 4 days or so, the fermentation is continued and completed by *Saccharomyces* species, especially strains of *S. cerevisiae*, *S. bayanus*, and in some cases *Saccharomyces paradoxus* (Moreira *et al.*, 2005).

Others

Vinegar

Vinegar is a highly acceptable condiment used in pickling and preservation of cucumber and other vegetables. Vinegar has long been used as a seasoning and preserving agent and is produced by a fermentation process from wine, apple juice, honey, rice, malted barley, etc. (Giordano *et al.*, 2003). In northeastern regions of Asia, such as China and Japan, vinegar is traditionally produced from cereals, primarily rice (Haruta *et al.*, 2006). Vinegar is not just a solution of acetic acid, but a complex matrix composed of alcohols, acids, aldehydes, and ketones (Wang and Jin, 2000; Suomalainen and Kangasperko 1963). The production of vinegar depends on mixed fermentation, which involves both yeasts and bacteria. Acetic acid bacteria, particularly those belonging to the genera *Acetobacter* and *Gluconacetobacter* (De Ley *et al.*, 1984; Yamada *et al.*, 1997) are used for industrial vinegar production because of their remarkable ability to oxidize ethanol to acetic acid and high resistance to acetic acid. The fermentation is initiated by yeasts, which break down glucose into ethyl alcohol with the liberation of carbon dioxide gas. Following on from the yeasts, acetobacter oxidize the alcohol to acetic acid and water. The yeasts and bacteria exist together in a form known as commensalism. The acetobacter are dependent on the yeasts to produce an easily oxidizable substance (ethyl alcohol). It is not possible to produce vinegar by the action of one type of microorganism alone.

For a good fermentation, it is essential to have an alcohol concentration of 10–13%. If the alcohol content is much higher, the alcohol is incompletely oxidized to acetic acid. If it is lower than 13%, there is a loss of vinegar because the esters and acetic acid are oxidized. In addition to acetic acid, other organic acids are formed during the fermentation, which become esterified and contribute to the characteristic odor, flavor, and color of the vinegar. Acetaldehyde is an intermediate product in the transformation of the reducing sugar in fruit juice to acetic acid or vinegar. Oxygen is required for the conversion of acetaldehyde to acetic acid. In general, the yield of acetic acid from glucose is approximately 60%. A combination of microorganisms such as moulds, yeasts, lactobacilli, and acetic acid bacteria is employed in traditional Chinese solid state fermentation, resulting in vinegars with better flavor (Jiang *et al.*, 2010). The principal bacteria are *Acetobacter acetic*, *Acetobacter xylinum*, and *Acetobacter ascendens*. The main yeasts are *Saccharomyces ellipsoideus* and *S. cerevisiae*. It is important to maintain an acidic environment to suppress the growth of undesirable organisms and to encourage the presence of desirable acetic acid-producing bacteria. It is common practice to add 10–25% by volume of strong vinegar to the alcoholic substrate to attain a desirable fermentation.

Microorganisms in Fermented Foods

Fermented foods are those foods that have been subjected to the action of microorganisms or enzymes so that desirable biochemical changes cause significant modification to the food (Chacko *et al.*, 2010). Filamentous moulds, yeasts, and bacteria constitute the microbiota in indigenous fermented foods and beverages, which are present in or on the ingredients, utensils, or environment, and are selected through adaptation to the substrate (Tamang, 1998). At present, all human cultures rely on fermented food products and the microbes that produce them (Scott and Sullivan, 2008). Different types of microorganisms are used in the production of different types of foods. **Table 1** shows selected species that may be used to produce various fermented food products.

Worldwide, lactic acid bacteria by tradition are the most commonly used microorganisms in the preservation of foods. Their importance is mainly associated with their safe metabolic activity while growing in foods utilizing available sugar for the production of organic acids and other metabolites (Balasubramanyam and Varadaraj, 1995). Their common occurrence in foods and feeds coupled with their long-lived use contributes to their natural acceptance as GRAS (generally recognised as safe) for human consumption (Aguuire and Collins, 1993). In Asia, mainly moulds of the genera *Aspergillus*, *Rhizopus*, *Mucor*, *Actinomucoe*, *Amylomyces*, *Neurospora*, and *Monascus* are used in the manufacture of fermented foods (Chacko *et al.*, 2010). In Europe, mould-ripened foods are primarily cheeses and meats.

Healthy Functions of Fermented Foods

Fermented foods have immense functional and therapeutic values possessing antioxidant, antimicrobial, probiotic, low-cholesterol, essential amino acid, bionutrient, and some important bioactive or health-benefit compounds; some of these are considered as potential sources of medical therapy for humans (Tamang, 2007).

Fermented Vegetables (Kimchi)

Kimchi was selected as one of the world's healthiest foods in 2006 by *Health* magazine due to its many beneficial properties (Nam *et al.*, 2009). Among the best functional components are β-carotene, chlorophyll, vitamin C, and dietary fiber (Park, 1995). Treatment of lactic acid from kimchi was found by Park *et al.* (2008) to play a role in the prevention of fat accumulation and to improve obesity-induced cardiovascular disease, particularly atherosclerosis, by attenuating the TNF α-induced changes of adipokines. Glycoprotein antimutagenic substances were isolated from a culture supernatant of *L. plantarum* isolated from kimchi (Rhee and Park, 2001), and antioxidants were isolated from kimchi (Sim and Han, 2008; Sun *et al.*, 2009). It has been reported that the consumption of kimchi causes weight loss; prevents constipation and colon cancer; reduces serum cholesterol (Park *et al.*, 2006); exerts antistress principles (Lee and Lee, 2009); is beneficial because kimchi contains *S*-adenosyl-L-methionine, a bioactive material used in the treatment of depression, osteoarthritis, and liver disease; has antiobesity effects (Kong *et al.*, 2008); and inhibits atherosclerosis (Kim *et al.*, 2008). A potential probiotic strain of *L. plantarum* isolated from kimchi inhibited the growth and adherence of *Helicobacter pylori* in an MKN-45 cell line, with small peptides as the possible inhibitors (Lee and Lee, 2006).

Fermented Soybean Products

Soybeans are well-known for their health-promoting benefits, which include antioxidation, antiobesity, antidiabetes properties, and prevention of osteoporosis and cancers such as breast and prostate cancer (Anderson *et al.*, 1998; Anderson and Pasupuleti, 2008; Messina, 1999). Many studies, which are insufficient and inconclusive, suggest that these kinds of health functions are primarily due to esterogenic properties of isoflavones but the results are still controversial (Kwon *et al.*, 2010). There are hundreds of *in vitro* studies showing that genistein has antioxidant properties, inhibits the growth of a wide range of both hormone-dependent and hormone-independent cancer cells, including breast (Pagliacci *et al.*, 1994; Peterson and Barnes, 1996; Zava and Duwe, 1997), prostate (Kyle *et al.*, 1997), colon, and skin cells (Adlercreutz and Mazur, 1997; Akiyama and Ogawara, 1991; Constantinou and Huberman, 1995) and that genistein also inhibits the metastatic activity of both breast (Peterson and Barnes, 1996; Scholar and Toewa, 1994) and prostate (Santibáñez *et al.*, 1997) cancer cells independent of the effects on cell growth. Daidzein, one of the two primary isoflavones in soybeans, exhibits anticancer effects (Jing *et al.*, 1993). Recently, genistein was also demonstrated to have antiinflammatory properties (Hernandez-Montes *et al.*, 2006; Verdrengh *et al.*, 2003), and it was found that genistein decreased cisplatin-induced apoptosis by regulation of p53 production in kidney, and reactive oxygen species production in cisplatin-treated normal kidney

Table 1 Selected species for various fermented foods

Food	*Microorganisms of fermented products in the world*	*References*
Fermented vegetables		
• Sauerkraut	• *Leuconostoc mesenteroides*, *Lactobacillus brevis*, *Lactobacillus plantarum*, and *Pedicoccus pentosaceus*, *Coliform* spp.	Wiander and Ryhanen (2005)
• Kimchi	• *L. mesenteroides*, *Leuconostoc pseudomesenteroides*, *Leuconostoc lactis*, *L. brevis*, *L. plantarum*, *Streptococcus faecalis*, and *Pfediococcus pentosaceus*	Kim and Chun (2005)
Fermented soybean and cereals		
• Tempe	• *Rhizopus oligosporus*, *Klebsiella pneumoniae*, *K. pneumoniae* subsp. *ozaenae*, and *Enterobacter cloacae*	Hesseltine (1965)
• Miso	• *Aspergillus oryzae*, *Saccharomyce rouxii*, *Torulopsis etchellsii*, and *Lactobacillus* sp.	Shibasaki and Hesseltine (1962), Hesseltine (1965)
• Doenjang	• *Bacillus subtilis*, *Staphylococcus sciuri*, *Enterococcus faecalis*, and *Citrobacter* or *Enterobacter*	Chang *et al.* (1977)
• Cereals	• LAB	Kohajdova and Karovicova (2007)
Fermented milk		
• Yogurt	• *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus* (formerly *Lactobacillus bulgaricus*)	Tamime and Robinson (2007)
• Cheese	• *Lactococcus* spp., *Pediococcus* spp., *Streptococcus* spp., *Leuconostoc* spp., *Propionibacter* spp., Cheese moulds, and yeasts	Caplice and Fitzgerald (1999)
Fermented fish		
• Surstromming	• LAB	Beddows (1985)
• Fish sauce (Indonesian)	• *Pseudomonas*, *Enterobacter*, *Moraxella*, *Micrococcus*, *Streptococcus*, *Lactobacillus*, *Staphylococcus*, and *Pediococcus*	Adams *et al.* (1985)
• Korean fish products from anchovy	• *Bacillus cereus*, *Clostridium setiens*, *Pseudomonas halophillus*, and *Serratia marcescens*	Adams *et al.* (1985)
Fermented meat	• *Lactobacilli* spp., *Pediococci* spp., *S. carnosus*, and *Micrococcus* varians	Leistner (1992), Sebranek (2004)
	• *Lactobacillus sake*, *Lactobacillus curvatus*, and *L. plantarum*	Leistner (1992), Sebranek (2004)
Fermented alcohols		
• Rice wine	• *Pseudomonas, Achromobacter*, *Flavobacterium*, or Micrococcus spp., *L. mesenteroides* var *sake* and *L. sake*, and *A. oryzae*	Kodama and Yoshizawa (1977), Wood (1977)
• Wine	• *Saccharomyces cerevisiae*, *S. bayanus*, and *S. paradoxus*	Fleet (1993), Moreira *et al.* (2005)
Others		
• Vinegar	• *Saccharomyces ellipsoideus*, *S. cerevisiae*, *Acetobacter* spp., *Gluconobacter* spp., *Xylinum*, and *A. ascendens*	De Ley *et al.* (1984), Haruta *et al.* (2006), Yamada *et al.* (1997)

Abbreviation: LAB, lactic acid bacteria.

HK-2 cells (Sung *et al.*, 2008). The previous review of the authors (Kwon *et al.*, 2010) described in detail the antiobesity effects of soybean for type 2 diabetes. Some studies of the effects of soybeans, including isoflavonoids and soy proteins, on glucose metabolism are inconsistent, and the mechanisms have not been extensively studied. However, other studies showed positive effects on hypocholesterolemia, for example, 46 postmenopausal women taking isolated isoflavone extracts had significantly increased high-density lipoprotein cholesterol and a decrease in apolipoprotein B, the primary apolipoprotein in low-density lipoprotein particles (Clifton-Bligh *et al.*, 2001; Goodman-Gruen and Kritz-Silverstein, 2001).

In soy protein nutrition, the sulfur amino acids, methionine and cysteine, are the limiting amino acids. However, the relatively low sulfur amino acid content of soybeans may actually provide an advantage in terms of calcium retention, ironically. The reported hypercalciuric effect of protein is likely to be at least partially due to the metabolism of sulfur amino acids. The skeletal system serves as one of the main buffering systems in the body; as a result, the hydrogen ions produced from the metabolism of sulfur amino acids cause demineralization of bone and excretion of calcium in the urine. Thus, bean protein may improve calcium retention relative to animal and grain proteins. Soy protein also has a cholesterol-lowering effect in monkeys (Terpstra *et al.*, 1984) and in men (Wong *et al.*, 1998), and protein hydrolyzate or hydrolyzed peptides of soybeans decrease blood cholesterol and glucose levels (Yoshikawa *et al.*, 1999). Lunasin, a 43 amino acid peptide from soy, has been shown to have numerous biological properties including anticancer and antiinflammatory activities (Mejia and Dia, 2009; Park *et al.*, 2001). In fact, the authors identified hypocholesterolemic, a peptide from fermented soy products, including doenjang and soy protein isolates, are known to activate peroxisome proliferator–activated receptors (PPARs) and liver X receptor

signaling and to inhibit sterol regulatory element-binding protein-1c signaling, contributing to insulin sensitization (Jhala *et al.*, 2003; Ronis *et al.*, 2009). In addition, soy-fed CD-1 mice exhibited enhanced insulin sensitivity, especially in white adipose tissue, due to the potentiation of phosphorylation of AMP-activated protein kinase and acetyl-CoA carboxylase and upregulation of the expression of genes involved in peroxisomal fatty acid oxidation and mitochondrial biogenesis and in skeletal muscles by increasing glucose uptake (Cederroth *et al.*, 2008).

It is also well-known that substituting vegetable oils, such as soybean oil, for animal fat reduces the risk of high blood pressure, thrombosis, platelet generation, and cholesterol accumulation (Meydani *et al.*, 1991). Soybean oils contain health-promoting linoleic, linolenic acids, and phytochemicals. Both short- and long-term fermented soybeans contain more beneficial components to ameliorate metabolic disorders than unfermented soybeans. The changes in nutritive and nonnutritive biofactors during fermentation and their capacity for ameliorating metabolic disorders were reported in Asian countries, especially Korea. Fermentation of soybeans increased isoflavonoid aglycones, modified isoflavonoids such as equol and small peptides, and these changes enhanced the prevention of metabolic disorders.

Fermented Dairy Products (Yogurt)

Probiotic foods are a group of health-promoting products called functional foods, with large commercial interest and growing market shares (Arvanitoyannis and van Houwelingen-Koukaliaroglou, 2005). Their health benefits are based on the presence of selected strains of lactic acid bacteria, and when taken up in adequate amounts, confer a health benefit on the host. They are administered mostly through the consumption of fermented milks or yoghurts (Mercenier *et al.*, 2003).

Among the health benefits, improvement of lactose intolerance symptoms among lactose maldigestors has been clearly demonstrated (Rizkalla *et al.*, 2000; Labayen *et al.*, 2001; Pelletier *et al.*, 2001). This physiological effect is thought to be not only due to the lowering of the lactose content in yogurt by 20–30% as compared to milk, but also due to the contribution of bacterial β-galactosidases to increase enzymatic activity in human intestines. Yogurt has also been used in the management of acute diarrhea disorders as recommended by the FAO/WHO (2003). Yogurt feeding in children with acute watery diarrhea decreased stool frequency and shortened the duration of diarrheal episodes (Boudraa *et al.*, 2001). A further benefit may accrue from its recognized immunomodulation capacity (Meydani and Ha, 2000). Yogurt consumption seems to enhance the immune response, particularly in immunocompromised populations such as the elderly (Tamang and Kailasapathy, 2010). Yogurt consumption has also been associated with decreased risk of progression and promotion of colon cancer by modulating cell proliferation and increasing cellular apoptosis (Rachid *et al.*, 2002).

Fermented Alcohols

It has been estimated that the medicinal use of wine dates back to 2200 BC, making it the oldest known medicine (Robinson, 2006). Historically, wine has been used as an antiseptic, a painkiller, and to treat dermatological conditions and digestive disorders (Feher *et al.*, 2005; Robinson, 2006). Epidemiological studies from diverse populations have revealed that individuals who habitually consume moderate amounts of wine experience a 20–30% reduction in all-cause mortality, particularly cardiovascular mortality, when compared with individuals who abstain or who drink alcohol to excess (German and Walzem, 2000; Ruf, 2003). It has been well documented that a moderate intake of alcoholic beverages produces positive effects on antioxidants, lipids, and platelets (reviewed in Lindberg and Amsterdamk, 2008). There is ample evidence supporting the health benefits associated with regular and moderate consumption of wine, particularly polyphenol-rich red wine (Guilford and Pezzuto, 2011). Phenolic compounds in red wine may prevent the oxidation of LDL and is linked with the reduction of certain cancers (Mannistö *et al.*, 1997). Clinical studies and work performed with animal models indicate that wine may protect against cardiovascular disease, atherosclerosis, hypertension, certain types of cancer, type 2 diabetes, neurological disorders, and metabolic syndrome (Guilford and Pezzuto, 2011).

Vinegar

Vinegar's antiseptic properties make it a powerful defense against bacteria, virus, and fungus. Because of its antifungal abilities, vinegar is commonly used to treat a number of scalp problems including itching and dandruff. Vinegar is also used as a pain reliever and is believed to help lower bad cholesterol, reduce high blood pressure, heal respiratory infections, relieve constipation, and prevent diarrhea. Vinegar is also believed to help the body balance its blood glucose levels. This can help people suffering from diabetes, as well as individuals who want to keep their glucose and energy levels stable throughout the day. Consuming vinegar is believed to flush toxins from the body, improve immune system function, eliminate yeast in the digestive tract, and cleanse the urinary tract.

Conclusion

Modern consumers worldwide are increasingly becoming interested in their personal health and expect the food they consume to be not only safe but also healthy or even capable of preventing illnesses. Fermented products have a very important role to play in human diet not only in terms of nutrition but also in the promotion of good health. One possible reason for the lower incidence of diseases such as obesity, diabetes, or even breast cancer among Asians is that they consume a lot of fermented foods including soybean products, which are unique to the Asian traditional diet. Fermentation makes it possible to provide and preserve large quantities of nutritious food in a wide variety of flavors, aromas, and textures to feed the increasing population of the world. However, careful selection of specific strains combined with proper production and handling procedures are necessary to ensure that desired benefits are provided to consumers.

Glossary

Gelatinization A disorganization and loosening of the internal structure of starch granules by heating, rendering the starch more amenable to enzymic hydrolysis.
Isomerization The transformation of relatively insoluble resinous materials in hops to more soluble and bitter compounds that impact the taste and appearance of beer.
Maillard reaction A nonenzymatic reaction between amino acids and sugars induced by heat that leads to color and flavor formation.
Malolactic fermentation A conversion of the more sour malic acid into the less sour lactic acid.
Procyanidin Molecules found widely in plant tissues that are formed by the polymerization of monomeric polyphenols and which have antioxidant properties and may contribute beneficially to bodily health.
Scion Part of a plant attached to another plant.

Introduction

It is increasingly asserted that static civilization developed some 6–8000 years ago in the Fertile Crescent on account of the 'discovery' of beer and bread, or some would say wine (McGovern, 2010). Surely, though, humankind has been sensing the pleasures of alcohol for rather longer than that, for unquestionably wherever there was a source of fermentable sugar (be it grapes or honey and more besides) and adventitious yeast, then there would have been circumstances for the production of alcohol and for humans to taste it and discover the mood-changing impact that could be had.

Through ages, the benefits of alcoholic beverages – now being produced routinely through emerging practices – will have been recognized as being one of the more pleasurable means by which foodstuffs could be preserved and modified.

To this day, most of the approaches to producing the diverse alcoholic beverages are deeply traditional in nature. Reference to the Sumerian poem The Hymn to Ninkasi emphasizes the broad similarity between beer production 8000 years ago and that which occurs today (Bamforth, 2008). Certainly the advances in fundamental scientific understanding, especially within the past 150 years, have allowed the refinement of beer making and that of other beverages. Yet the standard approaches have not hitherto become radicalized.

Through history the production of a beverage such as beer has progressed from being the purview of the women of households and broader communities, through refinement in monastic environs and onward to the advent of large-scale production brewers (once called common brewers) when the industrial revolution shifted workforces from domestic employment to factories with less opportunity for home brewing (Hornsey, 2003). Progressively, these large brewers became ever bigger, through consolidation as well as organic growth, events facilitated by technological developments such as design of ever larger fermenters; establishment of artificial refrigeration and pasteurization; development of railroad systems; and the evolution of more refined, flexible, and individual packages, such as kegs, glass bottles, and cans (Bamforth, 2009).

Some of these developments have also been applied to beverages other than beer, including wine and cider; however, many alcoholic beverages retain a more artisanal perspective. For drinks, such as beer and wine, too, there has been the same yearning for 'local' values, articulated in the beer industry with the word 'craft.' The reality is that beer production at any scale (just as for other alcoholic beverages) is a craft, pursued by technical people who rejoice in communities of like-minded individuals, in the case of brewing through organizations, such as the Institute of Brewing and Distilling (an organization that welcomes producers of other alcohol beverages, too, including cider), the Master Brewers Association of the Americas, and the American Society of Brewing Chemists. In the world of wine there is the American Society for Viticulture and Enology.

Taking brewing as an example, there are now more than 2500 breweries in the United States with many more at the planning stage. Government in the United States has had much to do with shaping the brewing and other alcoholic beverage industries. The era of prohibition between 1920 and 1933 saw a decline in the number of breweries from 1179 at the time of the signing into law of the Volstead Act to 703, 2 years after Roosevelt repealed the ban. Postprohibition rationalization led to a situation where only 89 breweries were functioning in the United States in 1978. President Carter's signing of an act in 1978 led to the legalization of home brewing the following year, from which came the seemingly endless spawning of smaller (and some not so small) brewing companies.

Governmental decisions can have profound impacts on businesses such as brewing. In the United Kingdom, Prime Minister Thatcher's government introduced the Beer Orders in 1988, which basically encouraged larger brewers to shift from becoming brewers per se to retailers as they were now forbidden to own an excessive number of pubs as had been the case in prior days of vertical integration (Bamforth, 2010). The realization that largest profits are to be made either from retailing beer or from brewing vast amounts of beer for wholesale distribution led to the major UK brewers selling their brewing activities to the larger global brewers, such as (the then) Interbrew, Heineken, and Carlsberg and diverting their

 doi:10.1016/B978-0-444-52512-3.00154-6

investment into pubs and hotels. Meanwhile the same phenomenal growth of smaller brewers has occurred as in, United States, leading to some 1000 breweries in a landmass that fits approximately twice into California.

The world of brewing is characterized, then, by (at one extreme) phenomenally large companies such as Anheuser-Busch Inbev, which produces approximately one quarter of the world's beer, and South African Breweries-Miller and the other tiny breweries so small that they slot into categories such as 'nanobreweries.'

There have been similar trends in other alcoholic beverage industries. And so there has been the advent of major alcoholic beverage companies, which focus on a diversity of products including wines and spirit, for example, Diageo and Constellation, although there is a plethora of almost boutique wineries in regions like the Napa Valley of California, as well as the advent of an incipient craft distilling sector.

Governments have a history of profoundly shaping the alcoholic beverages industry through their taxation demands. In Europe, there is tremendous discontinuity within the supposed 'borderlessness' of the European Economic Community when it comes to taxation (**Table 1**). This leads understandably to substantial crossborder shipping of purchased alcohol from countries with less demanding tax rates to those that levy substantially larger amounts (e.g., France–UK and Sweden–Denmark).

Tax, though, can have other substantive impacts on the shape of the beverage business, which again can be illustrated with reference primarily to beer. In Nigeria, in 1988 the banning of imports of barley and malted barley (to preserve scarce currency) led to a focus on alternative raw materials and approaches to the brewing of beer, featuring primarily materials readily available within the country. Similarly in Japan, tax laws have dictated that products containing $<25\%$ malt attract a significantly lower tax rate. These products, known as Happoshu, are produced using materials, such as sugar, rice, and corn. They cannot be called beer, but in every respect they are presented through package and image as beer, yet at a substantial discount. Even cheaper are the so-called Third Category products, taxed at a lower rate still because they contain zero malt but are rather fermented from the likes of pea starch and soybeans. As a consequence of these developments, there has been a precipitate fall in 'conventional' beers in Japan, with a continuing growth in these new genre products.

In the United States, a differential between tax rates for beer and spirits has spawned the so-called Malternatives. Because beer is taxed at a significantly lower rate than distilled beverages, the quest for flavored alcoholic beverages has led to the development of processes wherein a bland beer produced in a brewery is decolorized and then flavored as required, with flavors such as fruit or cola. Generally these products have either names that are recognized as being associated with spirits such as vodka or are accorded whimsical names. Either way they appeal to the young, who find them easier to drink than bitter beer (or tannic wine, for that matter).

As one shall see, the production of beer involves much use of water and energy, with alternate addition and removal of liquid, something that baffles many at a time of considerable ecological and environmental attention and desire to conserve resources. It would certainly be feasible to produce palatable products in radically different ways that are based on making additions to a bland alcohol source (Heymann *et al.*, 2010). However, such products in the United States would be prohibitively expensive on a tax basis.

The flavored alcoholic beverages certainly makes the government focus on the issue of alcohol and health. The UK government in 1987 issued guidelines for responsible drinking, amounting to a weekly consumption of 21 units for a man and 14 for a woman, where 1 unit is 8 g of alcohol. However, in the UK as in other countries, there are concerns about minorities who abuse alcohol, for example, through binge drinking in social contexts lending themselves to irresponsible behavior. As such, it is too easy for officialdom to lose sight of the fact that for the greater length of time, alcohol in some

Table 1 Rates of excise duty and value added tax in the European community

form or the other has been a staple feature of society and frequently a normal and not unusual component of the diet and the dinner table.

There is indeed increasing evidence that there are real merits in the consumption of alcohol in moderation (Ford, 2003). Although red wine more than any other beverage has captured the attention, notably in response to the countering of atherosclerosis, claims that this is due to its uniquely high levels of resveratrol have been challenged. It is now generally accepted that there is nothing unique about red wine in this context and that the key component is likely alcohol per se (Rimm *et al.*, 1996). As such, any beverage referred to in this article in the same equivalent terms in terms of alcohol content would be expected to have a comparable effect. That a product such as wine may be perceived as being superior has rather more to do with the other behavior of wine drinkers with regard to diet and exercise. In reality, beer possesses rather more nutritive value than wine in respect of factors such as high levels of silicate, which may counter osteoporosis, antioxidants which may be at least as effective as those from wine, significant levels of vitamin B such as folate, and the presence of significant amounts of soluble fiber and putative prebiotics (Bamforth, 2004; Preedy, 2008).

Despite this apparent superiority of beer over wine from a health perspective, there has been a very real shift in the drinking habits of people in traditional beer drinking countries, from beer to wine. This can be inspected in the context of overall trends in a breadth of countries (Table 2).

Table 2 Drinks consumption (per capita, 2010)

Country	*Beer*	*Wine*	*Spirits*
Australia	84.0 (−6.7)	23.7 (+17.3)	0.9 (−30.8)
Belgium	78.0 (−21.0)	25.7 (+18.4)	1.2 (0)

Beer

Barley starch supplies most of the sugars from which the alcohol is derived in the majority of the world's beers. Barley needs first to be malted, which comprises the controlled germination of grain followed by drying. The raw barley kernel is hard and not readily milled. During germination enzymes are developed that degrade the cell walls and protein during sprouting and go on to degrade starch in the brew house. Barley was originally selected for the brewing of beer because it retains a husk on threshing and this formed the filter bed in most breweries in which the extract of malt (wort) is separated from residual material after brewing (Bamforth, 2006).

Barley grain as harvested is dry (<12% moisture) or needs to be dried in order to preserve it and help prevent its infestation. The water content needs to be increased, usually to between 42% and 46%, in order to promote germination.

Not all barley varieties can be malted successfully. The so-called malting grades (as opposed to feed grades) are degraded readily, either because they have a structure amenable to hydrolysis or because they can produce higher levels of enzymes.

Barley used for malting should also have low protein content as, *pro rata*, for a grain of given size the less protein is present, the more starch there is. Therefore, fertilizer use for malting barley should be limited.

Barley also needs to be alive and also it should not be dormant. Dormancy is a natural condition designed to prevent grain from germinating when on the ear. It is prevalent when barley is grown in colder, wetter regions. Storage relieves the condition.

Kilning is essential to stop germination: by driving off the moisture, the metabolism of the grain is halted and the malt is stabilized for storage. Kilning must be carried out carefully because many of the malt enzymes that are needed to carry on polymer degradation in the brewery are heat sensitive. Therefore, heating is started at a relatively low temperature to start to drive off moisture. When the water level has perhaps been halved, the enzymes are more stable in this drier environment, and the temperature can be increased.

The other function of kilning is to introduce color and modify flavor. The more intense the heating, the darker is the color of the malt. Color is due to the melding of amino acids and sugars in the Maillard reaction. Therefore, the better-modified malts, with higher levels of polysaccharide and protein breakdown, will give darker malts during heating. The flavor changes involve removal of unpleasant characters, such as bean sprout and grassy notes, and development of pleasing malty aromas. A selection of malts is listed in Table 3.

Malting and mashing are really successive stages in a common enzymic conversion of barley into wort. The former is a low-temperature process, the latter a high temperature one. Before mashing, malt is stored for a minimum of 2–4 weeks to facilitate subsequent processing.

Malt must be milled before mashing. The smaller the particles the better the solute/solvent transfer from milled grist to the liquid. The conversion of the polymers that was begun in the malt house continues in the mash. This is often started at a relatively low temperature (e.g., 50 °C) to allow action of the more heat-sensitive enzymes, before raising the temperature to approximately 65 °C to induce gelatinization (melting) of the

Table 3 Malts used for brewing

Product	*Purpose/comments*
Pilsner malt	Mainstream malt for pale lager beers
Vienna malt	Mainstream malt for darker lagers
Munich malts	For darker lager beers
Pale malt	Mainstream malt for pale ales
Chit malt	Permissible as adjuncts in countries such as Germany with restrictions such as Reinheitsgebot
Green and lightly kilned malts	Alternate to exogenous enzymes
Diastatic malts	High enzyme potential for use in mashing with high levels of adjuncts
Smoked malts	For beers with smoky character, for example, rauchbier
Wheat malts	For wheat beers
Rye malts	For specialty beers
Oat malts	For specialty beers, including stouts
Sorghum malts	For *Sorghum* beers; malted millet may also be used as a richer source of enzymes
Cara Pils	To afford color and malty and sweet characters to lighter beers
Amber malt	To afford bread crust and nutty characters to beer and color
Crystal malt	To afford toffee and caramel characters to beer and color
Chocolate malt	To afford chocolate, roast, coffee, burnt, and bitter characters to beer, plus color
Black malt	To afford harsh, astringent, roast, and burnt notes to beer plus color
Roasted barley	To afford sharp, dry, burnt, and acidic notes to darker beers (n.b. drier than roasted malts)

Abbreviation: n.b., nota bene.

starch and attendant action of starch-degrading enzymes. For starches from some other cereals (e.g., corn and rice) the temperature is higher and this is why they are cooked separately before adding to the mash. During mashing, proteolytic enzymes continue the degradation of proteins and peptides into amino acids that the yeast will depend on for growth. However, some polypeptide needs to go through to the finished beer in order to support foam.

A trio of enzymes leads to the conversion of typically 80% of the starch in a mash to fermentable sugars in conventional mashing operations. Light and low carbohydrate beers are those in which the nonfermentable degradation products (dextrins) are fully or largely converted into fermentable forms. This can be achieved by the use of either glucoamylase or pullulanase of microbial origin or by adjustments to mashing that allow the endogenous enzymes to work more fully.

After perhaps an hour of mashing, the liquid portion of the mash, known as sweet wort, is recovered by separation over a time period either by filtering through residual husk or through membranes to the kettle. Here it is boiled, usually for approximately 1 h, and this serves various functions, including sterilization of wort, precipitation of potentially problematic proteins, and the driving away of unpleasant grainy characters originating in the barley. As there is a driving off of water the wort becomes concentrated. This is especially important for those brewers practicing high gravity brewing in which the wort is run to the fermenter at high strength; then after fermentation (in which higher than target alcohol levels are produced) the beer is diluted to the desired strength. This technique allows maximization of fermenter capacity. To facilitate these higher gravities, many brewers also add adjunct sugars at this stage, and most of them introduce at least a proportion of their hops.

The hops have two principal components: resins and essential oils. The resins are changed (in a process called isomerization) during boiling to yield the materials that provide the bitterness to beer. This process is rather inefficient. Nowadays, hops are often extracted with liquefied carbon dioxide and the extract is either added to the kettle or extensively isomerized outside the brewery for addition to the finished beer (thereby avoiding losses due to the bitter substances' tendency to stick on to yeast).

The oils are responsible for the 'hoppy nose' on beer. They are very volatile and if the hops are all added at the start of the boil then all of the aroma will be eliminated. In traditional lager brewing, a proportion of the hops is held back and only added toward the end of boiling, which allows the oils to remain in the wort. For obvious reasons, this process is called late hopping. In traditional ale production, hops are added to the finished beer, enabling a complex mixture of oils to give a distinctive character to such products. This is called dry hopping.

After the precipitate produced during boiling has been removed by straining through whole hops in a hop back or separation according to centripetal forces in a whirlpool, the hopped wort is cooled and pitched with yeast. There are many strains of brewing yeast (ale yeast *Saccharomyces cerevisiae* or lager yeast *Saccharomyces pastorianus*), and brewers look after their own strains because of their importance in determining brand identity. Ale strains collect at the surface of the wort if it is fermented in an open vessel, whereas lager yeasts settle to the bottom of the fermenter. This differentiation is blurred with modern cylindroconical fermenters, in which both types of yeast settle at the base of the fermenter when the beer is chilled after fermentation and primary maturation. Both types of yeast need a little oxygen to support membrane synthesis and growth, but otherwise alcoholic fermentation is anaerobic. Ale fermentations are usually complete within a few days at temperatures as high as 20 °C, whereas lager fermentations at as low as 6 °C can take several weeks. Fermentation is complete when the desired alcohol content has been reached and when unpleasant butterscotch and honey-like aromas due to the vicinal diketones diacetyl

Table 4 Major beer styles

Style	*Origin*	*Notes*
Ales and stouts		
Bitter (pale) ale	England	Dry hop, bitter, estery, malty, low carbonation (on draught), and copper color
India pale ale	England	Similar, but substantially more bitter
Alt (n.b. alt means 'old')	Germany	Estery, bitter, and copper color
Mild (brown) ale	England	Darker than pale ale, malty, slightly sweeter, and lower in alcohol
Porter	England	Dark brown/black, less 'roast' character than stout, and malty
Stout	Ireland	Black, roast, coffee-like, and bitter
Sweet stout	England	Caramel-like, brown, and full-bodied
Imperial stout	England	Brown/black, malty, and alcoholic
Barley wine	England	Tawny/brown, malty, alcoholic, and warming
Kölsch	Germany	Straw/golden color, caramel-like, medium bitterness, and low hop aroma
Weizenbier (wheat beer)	Germany	Hefeweissens retain yeast (i.e., turbid). Kristalweissens are filtered. Very fruity, clove-like, high carbonation
Lambic	Belgium	Estery, sour, and 'wet horse-blanket,' turbid. Lambic may be mixed with cherry (kriek), peach (peche), and raspberry (framboise), etc. Old lambic blended with freshly fermenting lambic = gueuze
Saison	Belgium	Golden, fruity, phenolic, and mildly hoppy
Lagers		
Pilsner	Czech	Golden/amber, malty, and late hop aroma
Bock	Germany	Golden/brown, malty, and moderately bitter
Helles	Germany	Straw/golden, low bitterness, malty, and sulfury
Märzen (meaning 'March' for when traditionally brewed)	Germany	Diverse colors, sweet malt flavor, and crisp bitterness
Vienna	Austro-Hungaria	Red-brown, malty, toasty, and crisply bitter
Dunkel	Germany	Brown, malty, and roast-chocolate
Schwarzbier	Germany	Brown/black, roast malt, and bitter
Rauchbier	Germany	Smokey
Malt liquor	US	Pale color, alcoholic, slightly sweet, and low bitterness

Abbreviation: n.b., nota bene.

and pentanedione, which develop during all fermentations, have been mopped up by yeast. The yeast is harvested for use in the next fermentation.

The 'green beer' is matured by a period of clarification through cold storage (typically $-1\,^{\circ}C$), before filtering. Filtration is generally aided by diatomaceous earth or perlite and various stabilizers may be used to remove materials that may cause haze, such as polyphenols or proteins. The filtered beer is adjusted to the required carbonation before packaging into cans, kegs, glass, or plastic bottles.

The array of beer styles is vast and major types are listed in Table 4.

Wine

Although wines have long been produced from all manner of plant materials, discussion in the present section is restricted to the products based on the grape (Boulton *et al.*, 1996).

Sound viticulture is a critical precursor to making wines of excellence. Many wineries tend to grow their own grapes or buy them from nearby vineyards. For growing wine grapes there should be minimal summer rain, hot or at least warm days, cool nights but little risk of frost. Other key factors are the depth, nutrient, and moisture content of soil and how readily it drains. Unless a soil is extremely acidic or alkaline, it is unlikely to be a major issue. Some regions are especially susceptible to diseases, such as Pierce's disease and phylloxera. Excess water uptake by grapes can also cause berries to swell and burst, which in turn enables rot and mold growth, for example, *Botyritis cinerea*. Winemakers refer to it as 'gray mold' when unwanted but 'noble rot' when deemed desirable! The character of certain wines depends on this infection, for example, the Sauternes from France.

Within the primary wine grape genus *Vitis* the main species are *Vitis vinifera*, *Vitis lubruscana*, and *Vitis rotundifolia*. Commercial vines tend to be 'scions' of *V. vinifera* grafted onto the rootstocks of the other *Vitis* species best suited to local soil and climate.

The time of harvesting has a significant role to play in determining the sweetness/acid balance of grapes. Grapes grown in warm climates tend to lose their acidity more rapidly than those from cooler environs.

Ripe fruit should be picked immediately before crushing. White grapes should be chilled before crushing, or they may be picked by night.

Nowadays the vessels used for extracting grapes and fermenting wine are fabricated from stainless steel and are jacketed to allow temperature regulation. Grapes are moved by screw conveyors from the receiving 'bin' to the stemmer-crusher. They pass from there either to a drainer, a holding tank, or (in the case or red grapes) directly to the fermenter.

Stems are not usually left in contact with crushed grapes so as to avoid off-flavors. This is not uniformly the case. For example, Pinot noir is sometimes fermented in the presence of stems in order to garner its distinct peppery character.

It is not necessary to separate the juice from skins immediately for red wine, but is so for white or blush wines. The color is located in the skin as polyphenolic molecules called anthocyanins. Blush wines are lighter than rose wines. For the latter, overnight contact between juice and skin with a modest fermentation allows the appropriate extraction of anthocyanins. After rose or blush juice has been separated from the skins it should be protected from oxidation by the addition of sulfur dioxide (SO_2). The rapid separation of skin and juice for white wines also minimizes the pick up of astringent tannins. The process may also impact other flavor compounds, for example, the flavors that impact Muscat. For certain grapes/wines, therefore, there is a balance to be struck in terms of oxygen availability, SO_2 use, contact time, and temperature.

The pH during fermentation should be maintained below 3.8. Wines then tend to ferment more evenly, there is a reduced likelihood of malolactic fermentation, and the wine develops better sensory properties. Furthermore at higher pH SO_2 is less inhibitory to wild yeast. Maintaining this low pH is especially important for white wines.

To accelerate juice settling so as to obtain a clearer product, pectinase enzymes are frequently added at the crushing stage to minimize the level of pectin, which originates in the wall material of the grape. The enzyme also allows easier pressing and affords higher yields.

Once the juice has separated from skins it is held overnight in a closed container. Thereafter, it is racked off (or centrifuged) before the addition of yeast. In locations where the grapes do not ripen well owing to a short growing season it may be necessary to add sugar (sucrose). Such a practice is illegal in some locales, for example, California.

The organic acids that are present are predominately tartaric acid in grapes grown in warmer climates but malic acid in grapes from colder climates.

The relevant species of yeast are *S. cerevisiae* and *Saccharomyces bayanus*. Contrary to commercial-scale brewing, dried yeast is extensively employed in wine-making, where adherence to a specific yeasts strain is frequently deemed of low significance. The chief limiting factor in wine fermentations is nitrogen, i.e., the amino acids are a must. The level of assimilable nitrogen is regularly increased by the addition of diammonium phosphate.

White wines are fermented at 10–15 °C, whereas reds are produced at 20–30 °C. Fermentation is inherently more rapid at the higher temperature, with the attendant increase in production of flavor-active volatiles such as esters. Rose and blush wines are fermented akin to white wines.

Fermentation tends to be progressively inhibited as the ethanol concentration rises, especially at higher temperatures.

The varietal character of certain wines is better preserved at lower fermentation temperatures. As in the case of beer, high levels of undesirables such as hydrogen sulfide can arise if fermentations are sluggish. In all cases, fermentation should be complete within 20–30 days. The progress of fermentation is monitored by measuring the decline in Brix value.

Wine is usually racked off the yeast once fermentation is complete. However, some winemakers leave the wine in contact with the yeast for several months, perhaps with intermittent rousing.

Color and flavor extraction from red grapes is maximized by mixing – either by pumping or stirring. Extraction is also greater at higher temperatures and increased ethanol concentrations.

White wines are either centrifuged or treated with the clay bentonite, which will also adsorb protein. Red wines are primarily fined in order to reduce their astringency. Fining agents include gelatin, egg white, and isinglass.

One of the biggest threats to wine is oxidative browning. The ingress of oxygen after fermentation should be minimized. Sometimes 'pinking' of white wines in bottle is prevented by adding ascorbic acid. But the chief antioxidant is SO_2, by reacting with the active peroxides in wine. Any hydrogen sulfide present in wine may be eliminated by the addition of low levels of copper.

Red wines usually undergo malolactic fermentation, performed by the lactic acid bacteria *Pediococcus*, *Leuconostoc*, *Oenococcus*, and *Lactobacillus*. In this process, malic acid is degraded to lactic acid with an attendant decrease in total acidity and a net increase in pH. The bacteria concerned prefer a relatively high pH and tend to be inhibited by SO_2. They also do not perform well at too low a temperature. Grapes from warm climates tend to contain less malic acid and therefore benefit less from such fermentation than do grapes from relatively cold areas.

The best Champagnes and sparkling wines are produced from the juice of Pinot noir or Chardonnay grapes. There must be rigorous avoidance of color development, hence the extensive use of SO_2. Fermentation in bottle is affected by a culture of *S. bayanus* that is flocculent and able to perform at high alcohol concentrations. The parent wine, invert sugar, and yeast are delivered into pressure-resistant bottles sporting a lip for the application of a crown cork. A headspace will be left in the bottle before it is laid on its side and held at 12 °C. The wine will ferment to dryness over a period of several weeks to more than a year. Then follows the process of 'riddling' in which the yeast is worked into the neck of the bottle. The yeast is loosened by hitting the bottom of the bottle with a rubber mallet or by using a shaking device. Then the bottle is put neck down into a rack at an angle of 45°. The bottle is rotated a quarter turn daily until the yeast sediment has all arrived at the cap. Then the inverted bottle is chilled to 0 °C and carried through a brine bath cold enough to yield a frozen plug of wine approximately 3.5 cm long. The cap is removed and as the ice plug is forced out it scrapes the yeast with it. The bottle is immediately turned upright again, refilled with wine containing sugar and some SO_2, corked, and labeled. Certain wines are carbonated simply by bubbling with carbon dioxide before packaging.

Contrary to most beers, wines tend to benefit from aging, which is performed either in tank, barrel, or bottle. The extent of aging is likely to be less for white wines than for reds. Some wines, for example, chardonnays, are aged in oak barrels, from which some characteristics are derived. Burgundy and Loire whites are led on the lees for up to 2 years ('sur lies').

Cork taints on wine can come from several sources. Trichloroanisole affords a musty or moldy character, geosmin an earthy note, and 2-methylisoborneol a chlorophenolic aroma.

Fortified wines are products in which fermented, partially fermented, or unfermented grape must be enriched with wine-derived spirit. The chief fortified wines are sherry (originating in Spain), port (from Portugal), and madeira (from the Portuguese archipelago of Madeira).

Sherry is only made from white grapes, but port and madeira may be produced from either red or white grapes. Wines on which sherry is based tend to be dry and the fortification occurs postfermentation. If the sweetness needs to be increased, this is done through the addition of grape-derived products downstream. Such additions usually comprise wines that have been fortified at the start of fermentation: by adding alcohol at the start of fermentation, yeast action is arrested, resulting in retention of sugar. Port is usually fortified approximately half way through the primary fermentation, and so tends to be sweeter than sherry through the preservation of unfermented sugars. Madeira may be fortified through either route depending on the sweetness desired.

The wines used to make sherry derive much of their character from aging in oat 'butts.' Sometimes, however, there is the development of *flor*, a film of yeast on the surface. In contrast, characteristics derived from the grape are substantially more important for wines going into port, especially red port. Much of the character of madeira develops in the estufagem process, which is a heating of the product at, say, 50 °C for 3 months.

Cider

Cider is an alcoholic drink produced by fermenting extracts of apples, though in the United States the term generally describes a nonalcoholic product, with the alcoholic product being termed 'hard cider.' Perry is the equivalent product made from pears.

The UK is the biggest producer of cider. The biggest selling style of cider is as a clear carbonated, light flavored beverage in bottle or can with an alcohol content of between 1.2% and 8.5% alcohol by volume (ABV). Increasingly, there is a trend toward chaptalization – i.e., the addition of sugars or syrups before fermentation to supplement the carbohydrate derived from apple. For the most part modern ciders may comprise only 30–50% apple juice. There has been extensive new product development in recent years, leading, for example, to higher alcohol products, 'white' ciders stripped of their color, the so-called 'ice' versions, and ciders flavored with diverse other components (Lea, 2011).

In France, ciders tend to be of lower alcohol content and to be distinctly sharp in flavor. Those from the Asturias region of Spain are relatively vinegary and foamy, whereas those from Germany tend to have relatively high alcohol content.

The best cider apples tend to have high sugar contents, of up to 15%, and a range of acidities from 0.1% to 1%. Their fibrous structure makes it easier to effect pressing, delivering higher yields of juice. It is possible to store them over a period of several weeks without losing texture, during which period their starch converts into sugar. Finally, they have a high tannin content (perhaps tenfold higher than in dessert apples), this being important for body and mouthfeel. Cider is usually produced from more than a single cultivar in order to achieve the preferred balance of acidity, sweetness, and astringency/bitterness.

Sometimes the substrate derived directly from the apple is supplemented with apple juice concentrate (AJC). Alternatively, the apple juice may be supplemented with cane or beet sugar or hydrolyzed corn syrup.

In modern cider-making facilities a high speed grater mill will feed a hydraulic piston press to crush the apples. The juice is afforded a coarse screening before it is run to tanks fabricated from fiberglass, stainless steel, polyethylene, or wood.

Some blending of juices may occur before fermentation and additions made. In particular, there may be a blending with sugars or AJC. The free amino nitrogen level may be raised to 100 mg l^{-1} by the addition of ammonium salts. Thiamine may be added but this must be separate from the addition of sulfite as the latter will destroy it. Other vitamin Bs that are required are pantothenate (2.5 ppm), pyridoxine (1 ppm), and biotin (7.5 ppb). Such materials are especially likely to be limiting if the cider maker is using significant quantities of AJC or sugars. If the apple juice and its additions are too 'bright' then it will be necessary to add some solids (e.g., bentonite) to act as nucleation sites, the escaping CO_2 relieving inhibition of the yeast and also serving to maintain agitation in the fermenter. Pectolytic enzymes are sometimes added to initial fruit pulp or to the juice immediately before fermentation.

SO_2 is traditionally added to prevent the growth of contaminating microorganisms. It is less critical from that aspect with the advent of dried wine yeast, but it is still important from a flavor perspective. The effectiveness of SO_2 increases as the pH decreases because it is the undissociated form of bisulfite that has antimicrobial properties. The pH is lowered to <3.8 by the addition of malic acid before the addition of sulfite.

Nowadays, the vast majority of cider fermentations are pitched with yeast rather than taking advantage of endogenous microflora. Many of the cultures now added were originally isolated from the cider factories themselves, but some cider makers use wine yeasts with well-defined characteristics. Since the 1980s, there has been widespread use of active dried wine yeast. Where temperature control is affected, this is likely to be within the range 15–25 °C.

Ciders may be subjected to malolactic fermentation. This is favored if there is no sulfiting in fermentation and storage and also by autolysis of yeast when the cider is allowed to stand unracked on its lees. As sulfiting is so widespread these days the malolactic fermentation is probably less significant than it once was.

The color of cider arises through the oxidation of polyphenols in the juice. It can be regulated by the addition of sulfite. If the latter is added immediately after pressing then nearly all color development is suppressed. If SO_2 is added later there is less reduction of color.

The color of finished cider is standardized by the addition of caramel or other permitted colorants. The color is removed from specialty products like white ciders by the action of adsorbents such as activated carbon.

The traditional high bitterness and astringency of ciders originates with the procyanidins. Procyanidins with a degree of polymerization (DP) 2–4 are bitter and are referred to as 'hard tannins.' Those with a DP of 5–7 are astringent ('soft tannins'). The relative delivery of bitterness and astringency depends both on the apple cultivar and on how the apples are processed. Oxidized polyphenols adsorb (become tanned) onto the apple pulp and this suppresses both astringency and bitterness. If oxidation occurs in the absence of the pulp, then there is a relative transition from bitterness to astringency as the units polymerize. Alcohol tends to enhance bitterness but suppress astringency.

As in the case of beer and wine, the yeast produces a range of volatile components (e.g., esters), and the key variables are yeast strain, fermentation temperature, and the clarity and nutrient composition of the fermentation feedstock.

Racking consists of removing the newly fermented cider from its lees. In modern cider making this may occur relatively quickly and in the absence of maturation, before blending and packaging. More traditional processing has the cider left on the lees for several weeks, with racking into tanks for months of storage with minimum contact with air.

Initial clarification of cider is by natural settling, by fining (bentonite, gelatin, chitosan, and isinglass), or by centrifugation. The ciders will be filtered before packaging and may be blended, aided by expert tasting. Most ciders are pasteurized and carbonated *en route* to final pack.

Mead

Mead (fermented honey/water mixtures) developed in many countries around the world and the product may be flavored with spices (e.g., cinnamon, cloves, and nutmeg) herbs (e.g., chamomile, lavender, and oregano), even hops, in which case it is known as metheglin. Mead incorporating fruit is referred to as melomel, and the fruits include blackberry, raspberry, and strawberry. If grape juice is included then a pyment results and products including malted barley are called braggot. Mead may be distilled or concentrated by freezing to yield honey jack (Gupta and Sharma, 2009).

Modern production of mead comprises adding honey to 3–4 volumes of water with whatever addition of fruit, hops, herbs, or spices is required. After boiling, the surface froth is skimmed off and brewer's yeast added. Fermentation is at 15–25 °C for 3–6 weeks before aging in oak casks at 10–15 °C for up to 10 years.

Sake

Sake is essentially a rice wine, yet production is more akin to that of beer with the conversion of rice starch into a fermentable form before the action of yeast to produce alcohol. Products typically have an alcohol content of 18–20% ABV, although this is often reduced to some 15% ABV before packaging (Akiyama, 2010).

There is much ritual and tradition in the production of sake. The water must be colorless, tasteless, and odorless. The rice is the short grain japonica variety that becomes sticky when cooked. It is polished more extensively than the rice employed for general food use so as to lower the levels of undesirable protein, lipid, and minerals.

Sake production involves parallel fermentations: saccharification of the rice starch and fermentation of the resultant sugar occur simultaneously. Koji (*Aspergillus oryzae*) produces starch-degrading enzymes that generate the fermentable sugar. Sake yeast (*S. cerevisiae* var. *sake*) converts the sugars into alcohol. These side-by-side events mean that the sugars are progressively released and made available for the yeast to ferment, without the latter being exposed to inhibitory high sugar levels.

White rice is reduced in weight by 25–50% to remove the outer layers that compromise clarity and flavor. Rice for the premium sakes receive the most milling. The milled grain is steeped until its moisture level attains approximately 30% before transfer to a wooden tub with holes in the base to admit steam. The tub is placed over a metal vessel containing boiling water for approximately 1 h and this leads to the gelatinization of the starch.

A proportion of this rice is used to make Koji, a culture of *A. oryzae*. One-fifth of the rice from the steaming stage is cooled to approximately 30 °C and transferred to a double walled solar-like room that retains heat. Dried spores of *A. oryzae* are scattered over the surface and kneaded in. Several hours later, the mix is transferred to shallow cedar trays that are put on shelves and covered with a cloth for up to 2 days. The mix is stirred twice every 4 h to equilibrate the temperature.

The making of moto starter is basically similar to making koji, but the process is prolonged so that still higher levels of enzymes are developed. Moto is the seed mash and represents $<10\%$ of the total rice. Steamed rice infected with yeast from the air is sealed in a cloth bag and buried within uncooked polished rice immersed in water. After 4–5 days the water is removed by filtration and the polished rice steamed. A second mash is then produced by adding this yeasty water to the remainder of the steamed rice and a proportion of koji rice. The moto is ready for use after 5 days. An alternative procedure that lessens the risk of contamination with lactic acid bacteria is to mix steamed rice, koji rice, and water, and divide it into shallow wooden tubs. The mixture is stirred every 3–4 h through the night before grinding the next day using wooden paddles attached to bamboo poles. The rice is rubbed against the bottom of the tubs until the grains are reduced to approximately a third of their size and the mash comprises a thick paste. The paste is then transferred to a single large wooden vat and left for 2–3 days at 8 °C. Hot water is now added to the mash, thereby raising the temperature and stimulating airborne yeasts. The mix is maintained at 25 °C for 20–25 days before using as a starter for the main mash.

To produce moromi, the koji and moto are mixed in large wooden vats over a period of 4 days with a regime of progressively increasing rates of addition of rice and koji rice to the moto. Temperatures are at first allowed to rise to 15 °C, but on the third day the temperature is lowered to 9–10 °C. After a period of up to 18 days, the mixture is filtered through weighted cotton sacks over a wooden 'sake boat.'

New sake is held for 10 days at a low temperature before pasteurizing at 60 °C and transferring to sealed vats that are

traditionally fabricated from Japanese cedar. Up to a year's storage leads to a mellowing of the flavor and a pick up of notes from the wood. Subsequent blending is followed by adjustment to final strength before bottling.

Modern vessels are likely to be fabricated from stainless steel and rectified alcohol is often used as a supplement. Activated charcoal may be employed in place of sake boats.

There are diverse types of sake, from the standard Futsu-shu, which is the major sake produced and is the equivalent of table wine, through premium products (from more highly polished rice).

Sakes are customarily served at 20 °C when compared for taste. The precise manner by which sake is served depends very much on the season, any food that it is accompanying and on the type of sake. Heating is the norm in the winter months, though not for better grades of the drink. Many experts would be of the opinion that warming sake distorts the taste and should be avoided. However, another opinion is that dry sake is better warm (not hot).

Chicha

This product is primarily made from maize, but can also be made from yucca and cassava. Other materials might also be incorporated as a source of carbohydrate or flavoring (Steinkraus, 1996).

Chicha de jora is traditionally produced from a yellow maize called jora and has a pale straw-like color, a milky appearance and is somewhat sour with a cider-like aftertaste. It typically contains only 1–3% ABV. Maize (corn) is sprouted and extracted, the liquid then being boiled before fermentation, traditionally in enormous earthenware vessels. Traditional production has famously incorporated mastication, with the formation of balls that are flattened and laid out to dry.

A Selection of Other Fermented Beverages

Palm wine (or toddy) is produced from the sap of the palm tree. It is common in various locations in Asia and Africa, and is referred to by diverse names. Fermentation is through the action of endogenous yeasts for a few hours, leading to sweet products of up to 4% ABV (Steinkraus, 1996). Distillation of palm wine yields products including arrack.

Pulque is a viscous and milky drink made in Mexico by fermentation of the sap of agave plants. Fermentation, by *Zymomonas mobilis*, is carried in vessels of oak, fiberglass, or plastic and is seeded by the addition of mature pulque.

Tepache is produced in Mexico from the flesh and rind of the pineapple together with coconut, sweetened with Pilloncillo (or brown sugar) and honey and flavored with cinnamon or clove. It is only mildly alcoholic (through the action of endogenous organisms) and it may be served mixed with beer, perhaps spiced with chili.

Kumiss is traditionally produced by fermenting mare's milk and is a staple in the steppes of Central Asia. As the sugar content of the milk is not especially high, these drinks are of modest alcohol content (0.7–2.5% ABV). Commercial production of the drink may likely be from cow's milk, perhaps fortified with sucrose. Unpasteurized milk is fermented for hours or days while physically agitating. The primary organisms are yeasts and lactic acid bacteria, leading to a relatively sour product.

Whisk(e)y

Whisky (Scotch) and whiskey (Irish and other forms of the product) is a beverage made by fermenting extracts of cereals, distilling, and maturing, normally in oak. The major cereals used are barley, wheat, rye, and corn (maize). Malted barley is employed as a source of flavor and enzymes, which are responsible for converting not only the barley starch but also that of adjuncts into fermentable sugars. The malts may be 'peated,' i.e., flavored with the smoke from peat burnt on the kiln (Russell, 2003).

Rye is quite widely used in eastern Europe and is sometimes malted. In the United States, corn is especially widely used. Wheat has largely replaced corn in Scotch grain whiskies as the cost of importing grain from the United States became prohibitive and it is also used in some American whiskies.

Malt is essentially mashed as in the case for beers. Wort from unmalted grain, however, is not separated from the spent grains because modern continuous distillation processes do not demand it. Fermentation and distillation are affected with all of the grain materials still present. Unlike for the brewing of beer, there is no boiling of worts.

The initial processing in the production of grain whiskies is significantly different from that for malt whiskies. The first stage in production is the hammer milling of the cereal. The cereal is mashed with 2.5 parts water typically at 40–45 °C with some malted barley included as a source of enzymes. The slurry is now pumped to a cooker wherein the mash is mixed and injected with steam to achieve gelatinization of the cereal. The temperature will be raised to 130–150 °C and held there for a relatively short period of time. The contents of the cooker are now discharged to a flash cooling vessel. The impact of this is to release any residual bound starch from the grain matrix. The temperature falls rapidly to approximately 70 °C. The slurry is mixed with a separate slurry of malt (10–15% of the total grist bill) that may be at 40 °C but alternatively may be at the conversion temperature for starch (65–70 °C). The malt enzymes then catalyze the hydrolysis of the malt starch and also that from the cooked grain. Food grade enzymes may also be added – and to some extent there may still be the use of unkilned malt as a source of enzymes. Mashing will typically be for up to 30 min. The whole mash contents are transferred to the fermenter. There is no boiling, so enzymes can continue to work.

Specific yeast strains particularly suited to whisky production have been developed. Hybrids emerged from *S. cerevisiae* and *Saccharomyces diastaticus* that produce a spectrum of enzymes fully capable of hydrolyzing starch to fermentable sugar. Thus the distilling strains enable high alcohol yield.

Fermentation on a small scale may be in closed wooden barrels, but on a larger scale it will be in stainless steel vessels known as washbacks. There is little temperature control during fermentation, other than to target the initial temperature,

which may typically be in the range 19–22 °C. Typically, the fermentation is complete within 40–48 h.

The stills used in the production of whisky are of two types: batch and continuous. Batch (or pot) stills employ double or triple distillation and generate a highly flavored spirit. Continuous stills provide lighter flavored spirits that are mostly employed in blending.

Whiskies are matured in oak casks. Although American bourbon and rye whiskies are put into new oak casks, Scotch, Irish, and Canadian whiskies are filled into casks that have previously been employed for Bourbon or sherry. The bourbon casks used for Scotch whiskies must be filled at least once with bourbon and the latter must have been in the cask for at least 4 years. Aging of whisky in most countries must be for at least 3 years. There is a significant loss of alcohol by evaporation in this time, referred to as the 'angel's share.' In the maturation there is the development of mellowness and a decrease of harshness.

In Scotland, the final products may be a blend of whiskies from more than 10 grain distilleries and up to a 100 malt distilleries. There is an astonishing interaction and cooperation between separate companies to enable this. The blending is deliberately complex so that the unavailability of 1 or 2 whiskies in any single blending will not be noticeable.

Bourbon is made principally from corn plus added rye and barley and is aged in charred barrels. A close relative is Tennessee whiskey (USA), which is produced using a sour mash process. Canadian whisky (Canada) is a light product from rye and malted rye, with some corn and malted barley. Corn whiskey (USA) is from maize and is aged in barrels that have not been charred. Rye whiskey (USA) is from rye mixed with corn and barley and is aged in newly charred oak barrels.

Cognac

The grape vines employed for the base wine for cognac production are nearly all from Charente and the adjacent regions of Deux-Sèvres and Dordogne. The grape varieties must be at least 90% of either Ugni blanc, Colmbard, or Folle Blanc. Ugni blanc is by far the major variety, affording wine high in acidity and relatively low in alcohol, which renders it most suitable for distillation. The microflora employed for fermentation is endogenous. Sulfur dioxide is not employed. Fermentation is relatively fast, the wines being maintained on the lees and subjected to malolactic fermentation. The sooner the distillation is performed after fermentation, the better the quality of the product (Lea and Piggott, 2003).

The still must have a capacity of <30 hl and must be heated by an open fire.

The wood employed for aging of cognac has great significance. The fineness of the grain impacts the extent to which phenolics and other tannins are extracted, as does the shape and size of the barrel made from that wood and the extent to which the wood is charred in the shaping process. The wood is generally dried in the open air for more than 3 years. New spirit is introduced to this new wood for a period of 8–12 months before transferring to older barrels, thereby avoiding excessive astringent and bitter characteristics. Oxygen enters through the stave and is used by enzymes contributed by molds in reactions that have a role in the aging process. There is also volatile loss through the stave. Several batches will be blended during aging.

Armagnac and Wine Spirits

Armagnac is in South West France. The main vinestocks used for armagnac are the same as for cognac. The wines must be distilled in the Appellation area, with the maximum content of distilled alcohol allowed being 72% ABV. Again the use of sulfur dioxide is forbidden (Lea and Piggott, 2003).

Two types of still are used: the continuous Armagnac still and two-stage pot stills. Heating is always by open fire, although nowadays it is likely to be fueled by propane gas rather than by wood.

Wine spirits are usually aged in oak casks. Coarse-grained wood is preferred because more oxygen can then enter into polymerize tannins. Oxygen ingress is also important for the oxidation of some of the alcohol to acetic acid, which in turn reacts with alcohol to generate flavorsome esters during aging.

Expert blending is performed and the alcohol concentration lowered to a minimum of 40% by the addition of distilled water. Caramel may to be added to enhance color.

Brandy

This is obtained from wine spirits blended or not with wine distillates distilled to less than 94.8% ABV, such distillates not exceeding 50 Proof maximum in the final product. The product is aged in oak for more than 1 year, unless the casks hold <1000 l in which case aging must be for a minimum of 6 months. The making of brandy is an opportunity to salvage defective wines or deal with production surpluses, although top quality brandies may be made from wine specifically produced for the purpose. Brandies must be $>37.5\%$ ABV (Lea and Piggott, 2003).

Rum

The chief producing countries for rum are Barbados and Santo Domingo. Nowadays the coastal planes of Guyana (Demerara) are rich in estates producing sugarcane (Lea and Piggott, 2003).

At harvest time the fields of sugarcane are set alight in order to sanitize the soil, the stems are scorched in this process and the canes subsequently wither and are harvested by machete, a strategy thought to yield a superior product when compared to rum made from cane harvested by machine. The canes are topped to remove the leafy parts and the cane are then ferried to mills.

In the processing, the canes are cut and crushed and the juice limed, clarified, and evaporated. Various fractions are generated, but the key product for rum is molasses. The nature of the molasses depends on cane variety, soil type, climate, cultivation, and harvesting conditions. They are delivered hot to the distillery either by pipe or by tanker and are stored at 45 °C. The molasses are mixed with water in line. Lighter flavor rums may incorporate cane juice (12–16% w/v sucrose).

Formerly, adventitious yeasts were used to effect fermentation, but nowadays pure cultures of *S. cerevisiae*, *S. bayanus*, and *Schizosaccharomyces pombe* are used. Before fermentation, the molasses are diluted to 45 Brix and their temperature elevated to 70 °C in order to destroy contaminating organisms. The pH is lowered by the addition of sulfuric acid and the whole clarified by putting into a conical-bottomed settling tank, from which the sludge can be decanted from the cone. Ammonium sulfate is added as a source of nitrogen. Fermentation is conducted at 30–33 °C to a final sugar content of 16–20 Brix and this is reached in 24 h with an alcohol yield of 5–7% ABV.

Distillation is conducted in pot stills that were traditionally of copper or wood but now more likely to be fabricated from stainless steel. As for whisky there are also column stills of stainless steel or copper (Coffey stills). Pot stills afford heavier rums that need prolonged maturation, whereas the column stills are employed for lighter rums, or to generate the neutral spirits that can be used for the production of gin and vodka.

Rum is aged in bourbon oak casks. It is racked at 83–85% ABV. As the main production locale is tropical, aging is quite rapid and may be complete within 6 months. There may first have been a blending of light rums produced in column stills with heavier rums out of pots. Furthermore, there may be transfers between casks for successive maturation periods.

Vodka and Flavored Spirits

Vodka is essentially pure alcohol in water, though flavored variants are available. Gin comprises distilled alcohol flavored with a range of botanicals. Similar to this are Aquavit (caraway or dill), Anis (aniseed, star anise, and fennel), and Ouzo (aniseed and mastic) (Lea and Piggott, 2003; Blue, 2004).

Vodka comprises pure unaged spirit distilled from alcoholic matrices of various origins and usually filtered through charcoal. Materials added in the production of vodka include sugar at up to 2 g l^{-1} and citric acid at up to 150 mg l^{-1}. Some vodkas have glycerol or propylene glycol added to enhance the mouthfeel. Among the flavored vodkas are those infused with pepper, buffalo grass and apple and pear leaves, brandy, and port.

A neutral alcohol base is frequently produced quite separately from the vodka per se, perhaps by a different company. It is chiefly produced from cereals (e.g., corn and wheat) but other sources of fermentable carbohydrate include beet and molasses in western countries, sugarcane in South America and Africa, and potatoes in Poland and Russia. The fermentation is effected by *S. cerevisiae*, notably distillers' strains. The alcohol is purified and concentrated by continuous stills before carbon treatment.

The word gin is a corruption of genievre, the French word for juniper. Distilled gin is produced by distilling neutral alcohol and water in the presence of botanicals. The product is diluted further with alcohol and finally brought to its final strength with water.

The alcohol for gin may come from grain-, molasses-, potato-, grape-, or whey-based fermentations. The prime traditional flavorings are the juniper berry, coriander seed, and Angelica, together with the peel of orange and lemon. Other materials may also be used in the formulation of gins and these include cassia bark, cubeb beris, liquorice, orris, almonds, and grains of paradise.

Water quality is critical for the production of gin and, as for beer, this explains the traditional locales where the drink was first made and became popular.

Gin is produced in copper pot stills similar to those used in the production of whisky. The botanics are added either loose or suspended in a bag.

Sloe gin is produced by steeping sloe berries in gin. The mix is sweetened with sugar, filtered, and bottled. Nowadays, flavorants may be employed in place of the berries per se.

Pimms is based on a secret recipe and is compounded from gin and liqueurs.

Liqueurs are produced by dissolving or blending several components. For the most part they are 35–45% ABV, although some are less strong. The alcohol must be from a fermentation process. The other key ingredients in these products are sugar (to deliver both sweetness and mouthfeel), flavors (that may be either the plant material per se or distilled essential oils or extracts from those botanics), and color (which again may be of 'natural' origin or via an approved colorant).

Cream liqueurs incorporate milk fat, sodium caseinate, and an emulsifier. Through homogenization procedures, the size of the fat globules is reduced to one that allows a stable emulsion to be obtained.

A representative list of liqueurs and some other beverages is given in Table 5.

Other Distilled Beverages

Schnapps is a clear colorless beverage, typically of 40% ABV produced by the distillation of fermented fruit, which accords some flavor to the beverage. Chief among the fruits used are apple, apricot, cherry, pear, and plum. The French equivalent is *Eau de Vie* ('water of life') (Lea and Piggott, 2003).

Tequila is a traditional Mexican distilled product derived from fermentations of blue agave plant. Margarita is a cocktail comprising tequila, Cointreau, and lime juice.

Absinthe is a distilled product of 45–74% ABV with an anise-flavor derived, *inter alia*, from wormwood, green anise, and sweet fennel. It is customarily green but colorless versions are available. It is customary to dilute absinthe with water before drinking. In most countries it is made in a manner analogous to gin, employing distillation in the presence of botanicals.

A traditional way of drinking absinthe involves putting a sugar cube on a perforated spoon that is held over the glass containing the beverage and approximately three times the volume of ice-cold water is poured through the spoon. The mixture becomes cloudy.

Cachaça is a spirit produced by the distillation of fermented sugarcane juice (as opposed to the molasses used in the production of rum) and it originates in Brazil. It is typically between 38% and 48% ABV.

Pisco is a colorless, sometimes yellow, grape brandy from Peru and Chile. Pisco in Peru is made using copper pot stills. By law the aging must be for at least 3 months in a container

Table 5 Some liqueurs and specialty alcoholic products

Product	*Notes*	*Country of origin*
Absinthe	Brandy flavored with sweet almonds and apricots	France
Advocaat	Brandy-base. Egg yolks, sugar, and vanilla	Holland
Akvavit	Anise, caraway seeds, coriander dill, fennel, and grains of paradise	Scandinavia
Amaretto	Apricot kernel and bitter almond flavor	Italy
Anis	Anise/Star Anise/fennel flavor	Diverse
Arrack	Distillation of alcohol from grapes, sugarcane, rice, or dates. Word means 'sweat'	Arabic
Bailey's	Irish whiskey and chocolate	Ireland
Benedictine	Brandy flavored with 27 plants (including cardamom, cinnamon, cloves, juniper, nutmeg, tea, and myrrh) and sugar. Colored using saffron and caramel	France
Bitters	Diverse, including *Angelica* root, artichoke leaf, cascarilla, *Cassia*, *Gentiana*, bitter orange peel, quinine, thistle leaves, wormwood leaves, and yarrow flowers	Various
Campari	Red product made by blending 68 herbs with quinine, Chinese rhubarb, cinchona bark, and orange peels	Italy
Cassis	Macerated blackcurrants in neutral spirits and brandy	France
Chartreuse	Blend of 130 herbs and honey in brandy	France
Cherry brandy	Distilled juice of cherries, fermented in presence of crushed cherry stones, perhaps blended with Armagnac	Mainland Europe
Cointreau	Blend of distillates from bitter and sweet orange peel, plus sugar	France
Drambuie	Scotch whisky suffused with herbs, spices, and heather honey	Scotland
Grande Marnier	Cognac blended with distillates of bitter orange and sugar	France
Malibu	Light rum/coconut	Barbados
Ouzo	Aniseed and fennel and mastic distilled in copper stills <1000 l	Greece
Pastis	Aniseed and liquorice	France
Raki	Aniseed	Turkey
Pernod	Spirit base suffused with star anise, fennel, chamomile, coriander, veronica, and other herbs	France
Sambuca	Anis, star anise, Elderflower, invert sugar	Italy
Southern Comfort	Grain-based spirit containing peach and orange and sugar	US
Tia Maria	Cane spirit/rum base with coffee and spices and sugar	Jamaica

that does not change the physical or chemical characteristics of the beverage and neither can any additions be used that influence the properties of the drink.

Glossary

Corporate social responsibility The approach a company takes in its contribution as a member of the community, especially in the areas of the environment and labor rights.
Food accessibility The ability to procure the food that is available in an area.
Food availability The presence of food in an area.
Food security The availability and accessibility of wholesome, culturally appropriate foods that are free from contamination.
Foreign direct investment A private industry's investment into a nation's infrastructure for purposes of engaging in the production and retail process of a commodity.
Horizontal integration Where many suppliers sell product to a limited number of other firms or intermediaries in the production chain.
Intergovernmental organization An organization with representatives and funding from member nations that agree to function under the mandate of the organization, examples include the World Trade Organization and the United Nations.
Oligopoly A situation where the market is shared by a small number of producers or sellers.
Transnational corporation A corporation whose production chain occurs in many different countries.
Vertical integration Where one firm owns the systems or processes in multiple steps of the production chain that were traditionally separate companies.

Introduction

Food chains are a set of complex interactions that bring food sources from the producer to the consumer. They are impacted by government policies, ecological potential, availability of technology, the skill of producers, and the ability of producers to invest in the production process (Food and Nutrition Division, 1997). There are two common ways in which the food chain can be described, as food supply chains or as food value chains. There is an important distinction between these two terms. Value chains are a marketing perspective. They look at what will add value to the product from the consumer's point of view, so in terms of production they are a retrograde examination. This evaluation of where in the production process value is added to the product has led to the development of concepts such as 'corporate social responsibility (CSR),' and the marketing of products that are labeled as 'Fair Trade,' 'Organic,' 'Dolphin Safe,' and 'Ecofriendly' to name a few (Smith, 2008). However, supply chains refer to the flow of goods from the producer to the consumer and the evaluation process aims to increase the efficiencies of this movement of goods. The supply chain point of view will be the primary focus of this article. Food sources, food processing, food transport, infrastructure requirements, as well as societal requirements and restraints will be the primary discussion of this article, but the impact of the value chain will not be ignored and its impact on the evolution of food supply chains will be discussed (**Figure 1**).

Food supply chains can range from simple, such as those seen with subsistence farmers who produce a large portion of their own food, to complex, where the global food chain and all of its international regulations that allow trading between countries and multinational corporations occur. The distance food must travel for consumption is based on its market worth and desires and many exotic foods are part of a global food supply (and value) chain purely out of consumer-driven wants. Yet, the food supply chain began as a need. Every living organism must consume food for energy and life – none are exempt.

Human history describes our earliest food supply as essentially hand-to-mouth. Hunter-gatherer societies caught or collected the food they would eat or their family would eat. During this time, conserved food processing was developed. This includes preservation techniques such as smoking, drying, and salting. Although at the time this was to allow food to last longer and to prevent food waste and perhaps starvation, it was these techniques that would eventually allow for trade of food products as well (Smith, 2008). The basis behind this original food chain was subsistence; one must eat to live.

As time passed and the crop domestication, as well as animal domestication developed, greater amounts of food were produced. At this point, a farmer was able to produce more than he needed, and could produce enough food to support more than his immediate social structure of responsibility (Diao *et al.*, 2007). When this occurred, all people did not need to take part in the food production process. Instead, the economy that grew from domesticated farming originated as a method to provide food for all persons despite not all persons being involved in farming. If people did not grow their own food or did not grow enough of their own food, they bartered for food by trading with their skill set. This persists today in areas of the world where money is not readily available and where the goal and struggle is still to meet the person's basic caloric needs. This is a food chain driven by need and not preference, caloric intake was the primary goal and the type and quality of food were of lesser concern.

When defining food security there are three main components: availability, access, and safety (Havas and Salman,

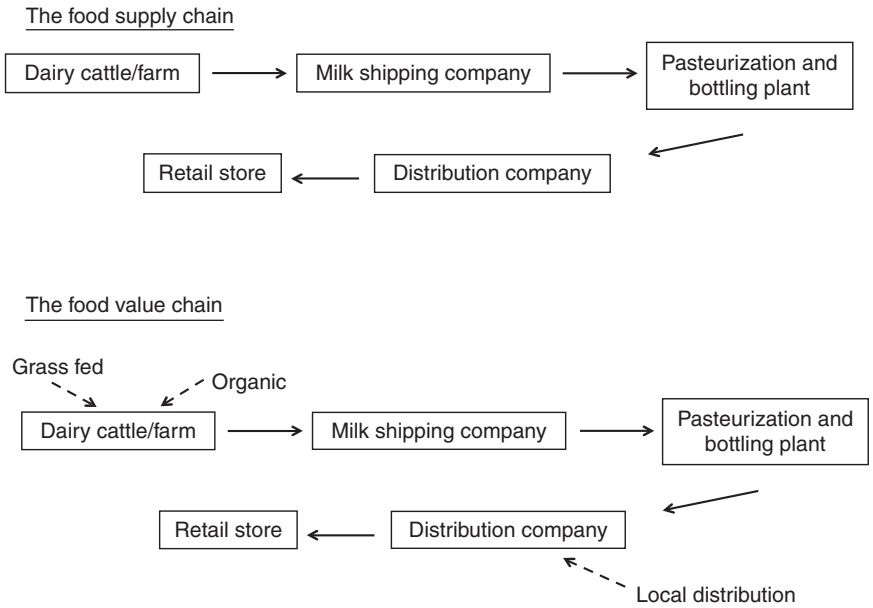

Figure 1 An example of dairy food supply vs. food value chains.

2011). Availability is the presence of the food within one's market reach. One's food market may be local, on the internet, through retail, or other resources, but one must be able to resource that item. Access is not just the availability but also the ability of one to buy the item. Food safety is the ability to buy food free from contaminants and reasonably free from pathogens. The food supply chain is focused on food availability, whereas the food value chain also ensures safety and considers access, as well the cost of foodstuffs at a price point with the greatest profit for the marketer but still within the reach of the target population.

Typically, in any food chain there are four primary roles to consider: the producer, the supplier, the processor, and the retailer. These roles can be condensed and one group may take care of each role, or there may be many steps and many individuals involved. The producer is the farmer, the one who grows the plant or raises the animal to harvest the raw material. The supplier is an intermediary. They buy the raw supplies and sell them to the processors. Processors prepare the food for consumption and sell the final product to a retailer for sale to the consumer. Processors are often defined as adding value to the agricultural product via postharvest processes before marketing (Wilkinson, 2004). Yet, based on the production practices, producers can also add market value to a product. The local supermarket exhibits this when one sees the phrases organic, cage-free, without hormones, or other product descriptions that come from the producer level.

A food chain can be a complex process. There are often many suppliers to one processor and many retailers who receive the final goods. National and international laws regulate the international trade and production of these goods and the international market's food chain is working to integrate small-scale farmers as well as corporations so that everyone can benefit. The 'Buy Local' movement and the ability of small farmers to integrate further complicate this.

The Food Chain

The University of Wisconsin published a tiered system to define a food chain. There are four tiers described in their system. The first tier is the locally procured food where the producer and the consumer interact. The second tier is the use of intermediaries to move locally and regionally grown food from the producer to the consumer. The third tier is for national grocery and distribution companies that have strong relationships with their consumers through product confidence and low prices. The contact with the farm is lost at this level. The final tier, the fourth tier, is the distribution of food globally where products are sold to retailers for sale but are not sold directly from the company itself to the consumer. There is a requirement of certificates defining the origin of location and there is no relationship with the consumer (Center for Integrated Agricultural Systems, 2010). This is a useful framework to discuss the framework of supply chains in countries of differing levels of development.

The type of market that predominates in an area may be related to the development of a country. There is not a singular purpose behind food consumption. Although it can be argued that the primary purpose is to meet caloric needs, there are many places where food is consumed socially, for cultural celebrations, for indulgence, and for traditions. All of these reasons for consumption drive the food supply chain, and have fed the food value chain. To simplify the discussion, the reasons behind food consumption and their associated food supply chains will be described as buyer-driven and producer-driven foodstuffs. Buyer-driven markets predominate in the developed world as they reflect social values that go beyond caloric intake of food. This could be argued to be a luxury of societies with enough food to eat. Once availability and access are achieved, then food has the ability to take on social values as well. Yet, producer-driven foodstuffs are universal. These are the staple crops and livestock meats needed by every

person in the world as well as the processed, mass-produced food markets.

Buyer-Driven Markets

Buyer-driven commodity chains are those that are controlled by retailers. They coordinate with many trading partners to meet consumer demands (Gereffi and Christian, 2008; Busch and Bain, 2004). This has become an oligopolic market, or a market where a small number of retailers, sellers, or suppliers meet the needs of the many consumers. The niche markets that develop in this type of market are in response to a backlash against mass food production. Often they are characterized by incorporating values into the food product and demand CSR, food safety, environmental sustainability, and using products to exemplify the social platforms. Organic, genetically modified organisms-free, and fair trade foods are examples of this (Busch and Bain, 2004). Foods that are exotic to the geography of the buyer but are thought to enhance health are often a part of the buyer-driven market. In the United States, this can include coconut water, quinoa, exotic fruits and vegetables, acai berries, and more. For these items, quality is the driving factor behind cost.

In buyer-driven food chains access is not an obstacle for the target population, but availability may be. In fact the lesser the availability of a product translates into rarity, as with most uncommon market items, they are also more expensive. Therefore, as the prices of market items rise, due to limited availability, the smaller the proportion of the population that has the income to access the item and the more targeted the supply chain is to those consumers. The retail market recognizes a consumer desire and makes that item available, but at a cost. This originated with spices and teas in the 1600s and it led to the creation of the East India Tea Company of Norway and Great Britain (Christensen, 2012). These were luxury items that were not necessities – nutritionally or culturally. Overall buyer-driven food chains are items that are not cultural or traditional food items, but are foods incorporated for some additional perceived social value or standing (Busch and Bain, 2004).

Interestingly, as the food value chain adjusted to this consumer demand, private industries raised standards beyond those of national concern or trade standards. Countries themselves cannot demand this exceedingly high quality of foodstuffs within their trade regulations purely for the purpose of quality. This raised the private standards of these foods beyond those set forth by the World Trade Organization (WTO) solely for the purpose of the value chains. Such quality demands create a challenge for farmers competing to supply these goods on an international scale. Private regulations applied to farmers can include food safety and quality issues, branding of the food product, and certifications such as fair trade and organic (Busch and Bain, 2004). It becomes difficult for most farmers to meet these high standards and pass the corporations' audits while still making a profit. The ones that most struggle to benefit from this trade is the small-scale farmer (Vorley and Fox, 2004).

However, these private standards have also sought to protect the farmer and the environment in a movement calling for CSR. These international trade standards under the auspices of the WTO result in global competition where countries leverage their comparative advantage to find their niche in the global market. For some, the comparative advantage is human labor, and this is a resource they compete with internationally. The result can be low wages or environmental depletion that is associated with processing and production (Friedmann, 2005; Roberts and Parks, 2009). The private standards, in many ways, have stepped in and created value around social platforms to protect these unskilled labor groups and their local environments. Fair trade has developed to ensure fair prices to small-scale producers; organic foods have given rise to demand reduce pesticide and chemical use; and ecofriendly farming certifications aim to highlight environmentally sustainable items (Friedmann, 2005; Raynolds and Wilkinson, 2007). Coffee, chocolate, and bananas are just a few of the products that have flourished under fair trade; and organic food items are almost commonplace in the supermarkets of the United States. Examples of environmentally friendly certifications are the Rainforest Alliance's Better Banana program (Rainforest Alliance, 2009) and the Marine Stewardship Council's sustainable fishing certification (Marine Stewardship Council, 2011).

An additional challenge that fair trade certification attempts to address with buyer-driven markets is that the suppliers and the retailers, not the producers, often drive the price points. This is in direct relation to the oligopoly that has developed surrounding the buyer-driven markets and the retailers' control. Producers are often small-scale farmers with little limited distribution markets who sell at the best price available. If global prices fall they are often the ones who have to produce for cheaper rates at the expense of labor costs or other benefits (Vorley and Fox, 2004). Typically, the price to the farmer or producer is less than 20% of the final profit on the item (Busch and Bain, 2004). This is associated with the ability of intermediaries to buy from many different sources and the competition that results is at the producer level. It is exacerbated by the lack of cost data at the producer level. The majority of pricing data collected is at the retail level, leaving a knowledge gap about the price points at lower levels of the supply chain (Busch and Bain, 2004).

Producer-Driven Chain

The complementary supply chain is the producer-driven chains, also known as bulk commodities, where mass production and not necessarily quality production is the focus. In food supply jargon these are considered food staples. They are the products that are either calorically dense or high in protein such as meat and poultry, rice, potatoes, wheat, and corn. The crop staples are more universally consumed, but as developing nations become richer, a demand for meat and poultry follows. As for the grains, small-scale producers grow many of these grains locally, but there is also a large international market. In fact, in 2011, US$1.3 trillion worth of food staples were imported across the globe (Trade and Markets Division, 2011). This high volume food supply chain grew out of the post-World War II practice of exporting food surpluses for sale in other countries as international aid. Food processing corporations are often typically behind these efforts. Perturbations in the market that causes fluctuation in the costs of these staple foods also lead to hunger (Friedmann, 2005), a major concern associated with the rise in the cost of food seen

during the global recession that started in 2008 (Trade and Markets Division, 2011). Global hunger concerns arise and large proportions of the global population go without enough to eat. This is because it is not available, nor can they afford the small amount that is available. These are foods that meet caloric needs and not culinary fancies.

As a result of the severe price fluctuations seen in food staples in the years of the Great Recession (2008–13), the International Group of 20 (G20) created an agricultural information system known as the Agricultural Market Information System (AMIS). The insecurity with the economy, the reduced supply associated with droughts, and the rising cost of fuel needed to transport these foodstuffs led to extreme volatility in food prices. The concerns of rising hunger were significant and the AMIS is meant to be a better predictor of these crises (Trade and Markets Division, 2011). The typical rules of supply and demand are muddied by extreme global phenomenon and reliance on food made half a world away, and now the international market can contribute to severe food insecurity in many places in the world. Food self-sufficiency is growing enough food within your own country and food security is having availability of enough food, which is now done through national crops and import crops. When the latter part of the supply is impacted as severely as it was during the global recession, food insecurity develops. (World Health Organization and World Trade Organization, 2002; Commodities and Trade Division, 2003).

The reason for the price instability is the relatively small number of large-scale producers that feed this supply chain. The international coarse grain trade includes corn, sorghum, barley, oats, and rye (Capehart and Allen, 2013). The United States is the world's major producer of corn, soybean, and wheat crops. The primary wheat exporters in 2012 were the United States, Argentina, Canada, the European Union, Russia, and Australia. Corn is a crop primarily exported by the United States and then Argentina (Foreign Agricultural Service, 2012). Rice as a staple crop was growing in popularity. The major exporting countries in 2012 included Thailand, Vietnam, India, and Pakistan; clearly Southeast Asia is a significant contributor to rice production (Foreign Agricultural Service, 2013). These are the foci of crop productions that feed the world. Therefore, weather, increased demand via population growth, increased demand associated with an increasing animal protein demand, and the increased use of crops as biofuels threaten food security and increase the cost of these commodity crops. As the national food security is based on imports as well as local growth and as greater profit can be made by selling goods at home, importing countries are often the ones who feel the dearth of the harvest the most. In addition, the importing country's consumers also absorb costs that accumulate in the supply chain, such as international trade requirements for testing, processing, and shipping. As oil prices rise, the costs of moving staples around the world also rise. Finally, new scientific processes that utilize plants, such as corn, for fuel also reduce the crop available for consumption and thus create a higher demand and higher cost.

Corn clearly plays a significant role in the global food supply chain. It feeds the animal supply chain and thus availability of animal protein, processed foods, and then the coarse grain market as well. International markets are at the mercy of the US crop and market prices as the US supplies approximately 75% of the world market with only 15–20% of its own crop. So domestic US demands impact the global supply (Capehart and Allen, 2013). A drought year in the United States and these increasing demands from animal production, biofuel, and processed food industries have an impact on the overall supply and play a role in determining price points. A legislative requirement to develop biofuels exacerbated food supply issues in years of poor harvest as well. So, corn is a crop that related best to supply and demand principles of economics. As supply drops and demand increases, so does the cost of the crop. With corn this is a trickle-down effect to the cost of meat, processed foods as well as adding additional demands on the supply chains of wheat and soy, thus increasing their prices as well (Action Aid International USA, 2012; Tenebaum, 2008). Availability in the food supply chain of these commodity or staple crops is volatile year-to-year and likely will remain so.

The relationship with the supply chain for producer-driven versus buyer-driven foods is based on the complexity of the product. Consumer-driven foodstuffs are often niche products. They are produced with a high level of quality, in smaller amounts, and sold to a specific market. These include items such as truffles, exotic fruits, coconut water, acai berries, quinoa, and others. In fact, bulk food staples, as will be discussed in the Section Transnational Corporations and Food Processing, can become niche product if they gain in popularity in areas outside the typical growing area. This has happened with quinoa and coffee. Their markets are highly regulated by the private sector and demand traceability. There are often 'voluntary' standards that inhibit entry to the market by farmers not already incorporated into an elaborate food chain. Owing to the small number of buyers and smaller target audience, the food chain is highly integrated between producers, suppliers, processors, and retailors (Vorley and Fox, 2004).

Finally, free trade agreements have benefited producer-driven industries. These agreements are authorized under the WTO, which ensures fairer trade, but not free trade (World Trade Organization, 2011a,b). The WTO provides a platform for nations to negotiate fair trade agreement based on their mutual risks and benefits without allowing politics and protectionism to play a role (World Trade Organization, 2009). The bilateral or regional agreements can further limit trade restriction so as to open markets to free trade agreement trading partners. Quotas and tariffs are often eliminated in these agreements allowing a free flow of goods through partner nations. The United States has numerous free trade agreements. The most well known is likely the North American Free Trade Agreement with Mexico and Canada. The result of this streamlined trading platform is also a global movement of goods creating a supply chain from one end of the globe to the other.

The Role of Food Security

Food security is the availability, access, and safety of foodstuffs (Havas and Salman, 2011). National food security means that a nation state has access and availability of safe, wholesome foodstuffs. National food self-sufficiency is the ability of a

national government to supply all of its nation's food needs through domestic production (Thomson and Metz, 1998). This is almost unheard of today. Today, food security is achieved through local production and import; countries rely on both. Yet, this is a macrolevel of security; having enough food being available in the country does not mean all localities have the same access. Food deserts crop up in impoverished, environmentally depleted, and infrastructure poor areas of a country. Food supplies in these areas may originate from local production, or, due to the lack of infrastructure, they may rely on processed foodstuffs. The results of poorly executed food supply chains are poor nutrition that results in starvation or obesity due to a lack of nutritionally balanced foodstuffs. Food deserts are defined not only by the lack of availability of foodstuffs, but also access associated with monetary costs and the time associated with accessing the food, preparing it, and cooking it while considering the time available in the household (Economic Research Service, 2009a,b). Therefore, national food security is a complicated concept and difficult to ensure at all levels between the individual and the nation.

Import is a significant means for many nation states to achieve food security. This international food supply has become highly regulated via intergovernmental organizations (IGOs), primarily by the WTO. When greater globalized trade took hold in the early 1980s, the post-World War II Global Agreements on Trades and Tariffs (GATT) was determined to be inadequate for the purposes of agricultural trade and intellectual property concerns. It also lacked an ability to enforce trade rules. The need to restructure in order to regulate a free market was central to these talks and the goal was to remove nontrade-related tariffs among member states. As a result of the round of Uruguay roundtable, the GATT negotiations of the 1980s led to the establishment of the WTO. The WTO was established in 1995 and it now regulates international trade and, thus, the international food supply chain, with the legal rights to enforce its regulations (World Trade Organization, 2009).

The WTO mandated other IGOs to create sanitary and phytosanitary standards for international trade: the World Organization for Animal Health created the standards for trade of animals and animal products, the International Plant Protection Convention for plant products, and a joint mandate for the Food and Agricultural Organization (FAO) and World Health Organization (WHO) for food products (World Health Organization and World Trade Organization, 2002; World Trade Organization, 2011a,b). The mandates to these organizations and the resulting standards created by each have resulted in a baseline requirement regarding plant, animal, and food health in order for trading to occur. If the nation importing the goods has more stringent requirements for testing or validation those requirements must be in place for domestic products as well. Under a concept called the 'most favored nation status,' nations cannot restrict trade for reasons other than those that are scientifically and medically based. All nations are favored nations should they meet the requirements for the product they are trying to trade. They cannot have any additional restrictions based on political or economic agendas should they meet the guidelines. In addition, the technical barriers to trade that are addressed by the WTO include standardizing label requirements and ensuring that domestic and imported products have the same requirements. This harmonization has made international trade and nontariff-related trade barriers predictable and limited (World Trade Organization, 2009, 2011a,b). This increases the efficiency of trade as well. The result has been a global growth in the movement of food and food-related products in the international trading system (Busch and Bain, 2004).

International Trade

International trade of food goods has been present for hundreds of years. The spice routes have been around since the Golden Age of Greece, where the first spice routes were created. The Romans took over with a bustling trade between Egypt and India. Up to 120 large ships moved spices from India to Egypt each year during this period. At the decline of the Roman Empire, Arabs gained control and kept it until Italians become involved in Constantinople. During the Crusades, the Palestinians kept the trade alive, and eventually the rest of Europe joined in as well. Marco Polo was the one who first described the supply chain. Essentially, India and numerous outlying islands farther to the east sold to traders in India, but India was not the sole supplier. By 1412, major ports of trade had grown in Morocco to facilitate trade from the east to Europe. The spices and goods from the east were so foreign and so sought after that many Christians of the day were convinced that they came from the Garden of Eden. Italy and Portugal were the primary initial players but interest in the markets expanded (Cliff, 2011). The trade between Europe and the East gave rise to multinational corporations of the day such as the Dutch and the British East India Companies (Cliff, 2011). In the late 1500s, this trade had extended to the new territories controlled by Spain in what is now Mexico, with Acapulco Bay being a major trading port as well. Typical galleons that anchored in the bay were from Manila and took 6 months to make the journey. Yet, these voyages were repeated every year from 1565 to 1815 (1616). Clearly, international trade was worth the investment and risk, even in the early years.

Since the beginning of global trade in the 1500s and 1600s many things have not changed. In the post-World War II era, there was a concerted effort to help countries recover through the development of economic reforms and trade standards, but the overall mass production for local consumption was the primary industry. This is most likely due to a lack of highly efficient transport and refrigeration at the time. In addition, communication and technology made shipment tracking and sales more difficult. As a result, the processed food industry arose. Many of these foods were shelf-stable, ready-to-eat, and based on convenience, whereas the domestic farms continued to provide the majority of fresh fruits and vegetables and meats. Much of the export was surplus foodstuffs and what was exported was called the Green Revolution, or agricultural development as a way to influence the political chess match of communism versus democracy in developing countries around the world (McMichael, 2009). The Green Revolution developed higher-yield crop varieties and brought inorganic fertilizers and pesticides into the norm. They assisted many countries avoid starvation, and the industrialized nations were

able to become food self-sufficient and to grow surplus crops (International Food Policy Research Institute, 2002). This drove the trade during this period of time, it was no longer trade from colonies to the colonial power, but instead exports flowed from the industrialized countries to the developed countries. So, the flow of goods reversed itself when considering the political power of the trade partners (McMichael, 2009).

As technology improved, the most current version of globalization took hold. International transport of goods was becoming time efficient and economically beneficial; refrigeration became possible; the internet made communication and shipment tracking a reality; and computers allowed for the management of a global business. So in the past 30 years, global trade of food has expanded significantly. It no longer includes solely shelf-stable and agribusiness products and agricultural surpluses. It includes almost any product one can think of: meat, eggs, poultry, fresh fruits and vegetables, beverages, processed snacks, and so on. It can all be integrated and coordinated to get products to the supermarket on time and to reduce loss in the supply of perishable items. An example of this was the invention of cold storage facilities. These facilities provide the opportunity to extend the shelf life of perishable goods so that the product has a longer period of time to make it to the market. Further, it allows for middlemen to be able to purchase these cold-stored goods with enough of a shelf life remaining to get them to another consumer market. An example of cold-storage facilities comes from India. Potatoes are more often kept in cold storage before making it to the consumer. In addition, to the added benefit of extend shelf-time, the cold-storage facilities have extended the availability of potatoes beyond their local growing season (Reardon *et al.*, 2012). As a result of technology, to include cold storage, the Supermarket Revolution was spawned.

Transnational Corporations and Food Processing

Foods involved in trade fall into two categories, processed and raw. Food processing is a system that adds value to food postharvest and before marketing. (Wilkinson, 2004). It processes agricultural and livestock products into intermediate or final food sources for the consumer. This is done through the input of materials, labor, and technology. The level of processing is not part of the definition (United States Department of Commerce, 2008). Value added by the processing increases the ease of preparation or consumption for the consumer and there are numerous food processing sectors. The leading sectors in the US industry are meat products, other food manufacturing, dairy products, grain preserving, fruit and vegetable preserving, and specialty products (United States Department of Commerce, 2010). Other food manufacturing includes syrups, snack foods, coffee, tea, condiments, and spices (United States Census Bureau, 2012).

The Codex Alimentarius was developed in 1963 to facilitate international trade through mandatory food standards. When the WTO was commissioned in 1995, it mandated the Codex Alimentarius Commission to continue their work and to define these standards underneath the new trade organizations umbrella. It is these standards by which trade of processed foods is often conducted, although other standards for semiprocessed meats and crops may apply as well. The Codex Commission is made up of delegations from all member countries. Historically, industries have been overrepresented. The 1989–91 Codex Commission had representation from 105 countries and 140 food and agrochemical companies. Further, there were 660 industry representatives and 26 public interest representatives (Sklair, 2002). So, the regulation of supply chains is largely impacted on an international scale by the transnational food processing corporations such as Nestle, ConAgra, Heinz, and Dole.

Transnational food processing corporations not only benefit from assisting in the establishment of intergovernmental trade standards, but also from their sheer size in terms of production. These large corporations take advantage of the economy of scale when buying ingredients from suppliers (Vorley and Fox, 2004), with transport, and with regard to the terms of trade. Not only can they buy in large amounts to produce large amounts, they also have the infrastructure to create competition among suppliers so as to find the lowest cost possible to create their product. Further, they are able to invest in technology that increases efficiency around the flow of the supply chain. This assists with production rates and benefits the profit margin as well. The complex nature of a supply chain is growing, the journal *Food Engineering* reported that 40% of companies that responded to a survey stated they were using radiofrequency ID trackers. These allow for tracking of the supply items through the use of computers and handheld scanning equipment (United States Department of Commerce, 2010). As a result of automation and improved technology, food production is much more rapid and efficient. In fact, some retail companies, such as Walmart, are requiring this technology from their suppliers (United States Department of Commerce, 2010), further limiting the pool of qualified suppliers in that food chain.

In the United States, transnational food-related corporations include commodity traders and food processors. Commodity traders are often horizontally integrated. They consolidate the product supply within the supply chain itself, so as to control the majority of the supply chain or at least a large portion of it. Commodity traders deal with minimally processed foods, such as grains, feeds, and slaughtered meat and poultry. In the United States 60% of the terminal grain handling facilities that ship product oversees are owned by only four companies: Cargill, Cenex Harvest States, Archer Daniels Midland (ADM), and General Mills. For corn exports, three companies manage 82% of the exports: Cargill, ADM, and Zen Noh. As for meats, Tyson, ConAgra, Cargill, and Farmland Nation manage 81% of beef packing as well (Commodities and Trade Division, 2003). This concentrated food supply chain reduces competition and this competitive pricing. This has a global impact, because many of these companies are leading US exporters and also the leading global exporter.

The vertically integrated corporations are those corporations that own or control large portions if not all of the processing procedure. These can be companies that provide processed or semiprocessed goods. Examples of such companies are Dole, Chiquita, and Tyson. For Tyson, they own the entire process from the chick to the packaged meat and money

only changes hands when the final product is sold to the retailer. The impact of such integration is the lack of data on price points at intermediate steps. For example, the cost of labor at a pineapple farm or the current cost of a chick is largely unrecorded and unknown in the global marketplace. This makes it difficult to know how much to charge when outside producers are trying to integrate into the supply chain, especially when there are larger producers who create the majority of the supply chain. Since they have no data to contribute to the cost point, it is at the whim of the buyer and not based on market rates. Further, when prices decrease within the production chain it does not necessarily trickle down to the consumer. There is no competition within the supply chain to drive prices or oversight of the process through market data. Finally, when a corporation owns the majority of the market, it has no competition forcing its prices downward (Commodities and Trade Division, 2003).

As a result of the transnational corporations (TNC's) ability to integrate horizontally and vertically, as well as to play a role in the international standard setting, the international food trade only has a limited set of players. The impact of the international trade on the marginalized farmer without the capital or infrastructure to compete is either of no effect, as they make a living off of the local market, or a negative effect when these corporations become national trading competitors with smaller scale farmers and retailers. Although the more readily available producer-driven food supply chain (rice, wheat, soy, and other grains) is a boon for urban consumers, it creates a problem for many of the world's small-scale producers. The imported foodstuffs are often cheaper than the locally grown items. It was predicted that small-scale producers would be able to compete in the fresh fruit and vegetable market trade as developed countries demand these products year round, even when out of local and national growing season. However, the role of small farmers has been less than was predicted due to the high industry standards for trade that they do not have the capital to allow them to achieve. The standards are no longer those of just the WTO, but are also the private industry standards, including supermarket standards. Monitoring a large number of small-scale farmers compared with a few large-scale facilities is easier for private industry, and this is what is occurring (Commodities and Trade Division, 2003).

Many TNCs, such as Nestle, Kraft, General Mills, and Pepsico, produce highly processed products. These complex food products are prepared from a variety of ingredients from multiple sources. Food products can also be produced in stages at various locations. Most commonly, these food supply chains are the food products that expand beyond 'staple' food products. The demand is growing with urbanization. There has been an increasing need to have foodstuffs that are easy to move, easy to prepare, and that are resistant to decay. Further, of the foodstuffs available, processed foods are also the cheapest and the least nutritious. These are popular items in food deserts, urban areas, and often in areas of poverty – limiting the nutrition in those areas (Economic Research Service, 2009a,b).

Not only are processed foods the major imports and exports for most countries, but the processed food sector is also a significant proportion of the overall manufacturing sector. According to FoodDrink Europe, the food and drink industry is the leading industry in the European Union in terms of monetary turnover (€956 billion) and contribution to employment (>4 million). It is the leading global exporter of foodstuffs and contributes 17.8% to the global food and drink trade (FoodDrink Europe, 2012). The focus of processed food companies is to create a 'consumer-ready' and 'value-added' product from the raw ingredients. They compete against one another in the industry based on the total sales. In 2012, Pepsico was the leading food processing company with US$38 396 000 in sales. The other top five companies were Tyson Foods, Nestle (Canada and the United States), Kraft, and Anheuser Busch. Nestle had the largest net profit of US $10 500 000 (Food Processing, 2012). This industry is not solely about food security and supply for countries; it is also about economy, employment, industry, and business.

Supermarket Revolution

This processed food industry would not be as profitable without a platform to sell food goods to consumers. The distribution of these food goods is through the retail market. This includes local, national, and international grocery chains. The traditional grocery store still sells approximately 58% of the processed food goods in the United States (United States Department of Commerce, 2010). The increased trade around the world has had a profound effect on retailers though and it is referred to as the Supermarket Revolution.

The Supermarket Revolution began in the 1990s. Retail supermarkets and their chains began moving beyond the developed nations of the world and into the developing nations. This revolution began as urbanization and an increase in income in the developing world, but its success was based on the foreign direct investment (FDI) that occurred with the entry of supermarkets. This FDI was made possible through the liberalization of the market associated with the development of the WTO, and through improvements in technology that allowed for improved supply chain management. This last point allowed the international supermarkets to have competitive prices in the local markets. For example, in Latin America and Southern Africa Walmart has been a leader in the FDI (Commodities and Trade Division, 2003; Wilson, 2012); Carrefour and Ahold are also major investors in Central and South American supermarket chains (Commodities and Trade Division, 2003). The supermarkets initially outcompete local retailers in the processed food sector and, within 10–20 years, the supermarkets in Central and South America, Southeast Asia, and Southern Africa have began to outcompete the local retailers in the fruit and vegetable market as well. In the end, supermarkets outcompete by offering lower prices for goods and higher diversity. This competition drives down the overall food prices and can lead to increased food security, especially for the urban poor (Reardon and Gulati, 2008). Yet, the accessibility of nutritious foodstuffs to the urban poor is limited, and the poor tend to rely on processed foods and ready-to-eat foods that have a lower nutritional value but are readily available (Kennedy *et al.*, 2004). The increased availability and access to food associated with the supermarket revolution does not necessarily translate to nutritional equality as well.

This revolution developed in three waves. The first wave began in South America, Central Europe, and South Africa in the early 1990s. At that time supermarkets accounted for only 5–10% of the market share, and by the 2000s they were greater than 50% of the market. The second wave was in Central America, Southeast Asia, and Mexico. By the 2000s, supermarkets in these regions accounted for 30–50% of the market share. In some regions of South and Central America the market share rose as high as 70% (Commodities and Trade Division, 2003). Finally, the third wave was made up of China, Vietnam, India, and Russia. As of 2011, supermarkets were emerging in Southern and Eastern Africa as well. There were patterns to the emergence of these supermarkets: they started in urban areas and spread to the rural areas; they were first accessible to the rich, then the middle class and finally the poor; initially they featured processed foods; then semi-processed foods and finally fresh foods (Reardon *et al.*, 2012; Milligan and Brown, 2011).

Yet this boom of supermarkets, which has likely improved global access to food, is not without its shortcomings to the small-scale producers and the traditional retailers. They have struggled against the competition in some locations. Urban retailers are most affected, and they only can gain a foothold in the market if they modernize. Outside support may be needed by these local retailers to modernize in an effective way (Reardon and Gulati, 2008). Yet, the impact of the Supermarket Revolution extends down the supply chain all the way to the farmers. Approximately 80% of supermarket goods are processed, shelf-stable products purchased from food processing corporations such as Kraft, General Mills, Nestle, Proctor and Gamble, ConAgra, and others. Most farmers that contract with food processing corporations are medium- to large-scale producers as they can support the larger contracts and can afford to meet the privately enacted standards driven by the CSR movement. As a result, small-scale farmers are poorly represented in this supply chain. Only, small-scale farmers with the largest land ownings, equipment, and access to infrastructure such as roads and irrigation are the ones that are able to break into the international supply chain (Reardon and Gulati, 2008; Commodities and Trade Division, 2003). There is great opportunity associated with the Supermarket Revolution for all farmers, but it is dependent on its ability to exclude or include the small-farmer sector of the country (Commodities and Trade Division, 2003). Overall, farmers involved in a supermarket supply chain can earn anywhere from 20% to 50% more in terms of net income than farmers selling goods via traditional routes (Reardon and Gulati, 2008). Thus, extending the opportunity down the supply chain could potentially benefit all farmers.

A Description of Global Export
